The Usefulness of Human Biomonitoring in the Case of Mycotoxins

Exposure Assessment

Human Biomonitoring – What it is?

Exposure to contaminants can happen through different routes, such as inhalation, ingestion, and dermal absorption. The exposure routes are mainly defined by the context where exposure to a specific contaminant can take place (e.g., through food consumption or in the workplace) and by the contaminant physical and chemical properties (e.g., if it is volatile, exposure through inhalation can be facilitated). The amount of contaminant uptake is often termed as the “absorbed dose.” The body burden of a specific contaminant is determined by factors, such as the contaminant’s concentration in a specific environmental medium, its physical and chemical properties, and timing of exposure, as well as individual factors, such as uptake, metabolism, and excretion rates (Calafat, 2016; Ganzleben *et al.*, 2017). Human biomonitoring (HBM) considers all these important aspects by measuring the concentrations of a chemical or its metabolites in biological samples (WHO, 2015). HBM can be defined as “the method for assessing human exposure to chemicals or their effects by measuring these chemicals, their metabolites or reaction products in human specimens” (WHO, 2015).

Biomonitoring data directly reflect the total body burden or biological effect resulting from all routes of exposure, inter-individual variability in exposure levels and metabolism and excretion rates (WHO, 2015). Therefore, biomonitoring involves measurements of biomarkers in several biological samples, such as blood, urine, saliva, breast milk, sweat, feces, hair, teeth, and nails. The choice of biological sample is mainly dependent of the chemical toxicokinetics, metabolism, bioavailability, and the collection procedure that should be the less invasive as possible (WHO, 2015; Calafat, 2016). In this context, is easy to understand how important is the choice of biomarkers for the quality and pertinence of data to be obtained within a HBM study (IPCS/WHO, 1993, 2001). Only with the right biomarker is possible to formulate the correct assumptions about exposure (Calafat, 2016; Louro *et al.*, 2019). Additionally, there are some important aspects to consider for a successful HBM study such as the adequate selection of the study population, procurement and type of biological samples, and the choice of analytical methods (Calafat, 2016).

To sum up, HBM provides an integrated measure of exposure to chemicals from all sources and routes and when properly used, biomonitoring data can be reliably used to estimate internal doses in environmental epidemiology studies (Calafat, 2016).

Biomonitoring as an Exposure and Risk Assessment Tool

For a specific chemical, HBM can identify spatial and time trends, lifestyle contributing factors, and specific groups with higher risk. For knowing this implies considering chemicals proprieties and adapt sampling strategy to guarantee the representativeness of the results and their adequate interpretation. For instance, for chemicals that are excreted rapidly, cross-sectional biomonitoring data reflect recent exposure, while characterization of long-term exposure patterns at the individual level requires repetitive sampling (Calafat, 2016). All these considerations allow determining the exposure at individual level and consequently this is of high relevance for the risk assessment process (Martins *et al.*, 2019).

Recently, Louro *et al.* (2019) described the state of the art of HBM use in existing risk assessment schemes, presented examples of the use of HBM for risk assessment and the results of a survey made to regulatory risk assessors on the use of HBM in risk assessment. It was possible to conclude that although the HBM data in chemicals risk assessment can be found in almost all regulatory areas, the guidance on such use is generally either limited or missing. To surpass this some recommendations were made such as create an EU level guidance applicable to different regulatory schemes on the use of HBM in risk assessment to better support the integration of HBM in regulatory risk assessment. Additionally, scientifically sound health-based biological limit/guidance values (such as derived via the biological equivalents approach), preferably with at least some regulatory recognition should be established at EU and/or global (e.g., WHO, FAO) level. The same paper also recommended future research actions intending to the development of approaches to integrate existing HBM data, data using non-animal testing methods (in vitro for instance) in combination with computational modeling (PBTK) to generate more reliable information on toxicokinetic and to provide connections between adverse outcome pathways and human internal

exposure levels. HBM data should also be used to validate integrated and aggregated external and internal exposure models (Louro *et al.*, 2019).

Biomonitoring Data to Support Risk Management Measures and Regulatory Actions

HBM is also an important tool to support environment and health policy-making because it can provide useful quantitative information regarding the actual exposure of a specific population to contaminants including emerging ones, as well as data regarding the resulting health effects and/or population susceptibility to these xenobiotic compounds. Therefore, HBM allows direct and more precise assessment of the distribution of risk in the population (WHO, 2015).

All this information can be used to prioritize actions and measures for policy making, to evaluate the effectiveness of the policy measures already in place and, consequently, to reduce exposure to hazardous substances (Ganzleben *et al.*, 2017).

In order to identify the most important exposure pathways as a basis for selection of the most relevant risk management measures and controlling emissions at source, HBM data on internal exposure should be combined with information on individual behaviors, diet, workplace environment, lifestyle, and monitoring data about environmental and/or food contamination. This contextual information combined with the development of exposure modeling can facilitate the identification of the most relevant exposure sources and pathways and support a review of the efficacy of legislation focused on specific chemical products or legislation dedicated to exposure pathways, such as air, drinking water or food or even the occupational environment (Ganzleben *et al.*, 2017; Viegas *et al.*, 2019).

In a more specific way, HBM can also support the implementation of new risk management measures and to evaluate the efficacy of the ones already in place in the workplaces. Therefore, HBM should be considered as an exposure assessment tool giving valuable information to the risk assessment and risk management process (Viegas, 2019). Unfortunately, HBM is seen frequently as only a health surveillance tool and not as an exposure assessment tool and this brings difficulties regarding the use of the information for risk management purposes (Santonen *et al.*, 2019; Viegas *et al.*, 2019).

What is a Mycotoxin and How We Can be Exposed?

Mycotoxins are fungi metabolites produced by specific fungal genera, mainly by *Aspergillus*, *Penicillium*, *Alternaria*, *Fusarium*, and *Claviceps* (Bennett and Klich, 2003; Marín *et al.*, 2013; Viegas *et al.*, 2018). These natural toxins are small and stable molecules, with a low molecular mass. Until now, more than 300 mycotoxins have been identified and probably more will be discovered in the future. However, only 30 of these mycotoxins have been the focus of research work aiming to understand their possible toxic properties (Surai *et al.*, 2008). Mycotoxins can resist to adverse environmental factors such as high or low temperatures and can persist long after the death and disintegration of the fungal species responsible for their production (Halstensen, 2008). Therefore, this explains why measuring only fungi do not allow to conclude about exposure to mycotoxins. They are also difficult to eliminate or inactivate from the source even after being exposed to high temperatures such as boiling or roasting processes (Peraica *et al.*, 1999).

The most common and reported exposure source is the diet, either by direct exposure (through the consumption of contaminated agricultural food products) or by indirect exposure (through the consumption of food derived from animals fed with contaminated feedstuffs, e.g., milk or meat) (Marín *et al.*, 2013, 2018).

From a public health and economic perspectives, the more important mycotoxins are aflatoxins, trichothecenes, zearalenone (ZEA), patulin, ochratoxin A (OTA), and fumonisins (Schatzmayer and Streit, 2013; Wu, 2014; Abrunhosa *et al.*, 2016; Lee and Ryu, 2017). At European level, the occurrence of mycotoxins is regulated by the European Commission aiming to protect consumers from its health effects, by the Regulation 1831/2003 and its amendments (European Commission, 2006).

In 2004, it was put in place a survey program, monitoring the presence of five mycotoxins/mycotoxin groups (aflatoxins, ZEA, deoxynivalenol (DON), fumonisins, and OTA) in feed and feed raw materials worldwide. The samples comprised essentially raw materials also used to make feed, such as wheat and wheat bran (9%), barley (8%), silage (8%), soybean meal (4%), distillers dried grain with solubles (DDGS; 2%), corn gluten meal (1%), rice and rice bran (1%), straw (1%), and other feed ingredients (e.g., cotton seed, sorghum, cassava, peanut, copra, etc., 12%). The samples were originated from different places in the world, namely Asia (45%) and Europe (37%), with 15% from Americas, 2% in Africa and 1% in the Middle East (Schatzmayer and Streit, 2013). From the results, it was possible to conclude that mycotoxin occurrence and contamination is strongly dependent on regional climatic conditions (frequently linked to extreme weather events or at least uncommon weather conditions) and that mycotoxins are ubiquitously present in feed and co-occurrence is a common feature. The data also allowed to conclude that the prevalence of mycotoxins in food is comparable to the one found in feed, even though at a lower level (Schatzmayer and Streit, 2013).

Aflatoxin B1 (AFB₁) is probably the most hazardous mycotoxin found in agricultural products since it is recognized as an hepatocarcinogen, inducing DNA adducts leading to genetic changes in target liver cells (Chen *et al.*, 1997; Vineis and Xun, 2009). It is commonly found on several food commodities worldwide being the most reported the grains and peanuts (Rocha *et al.*, 2014). *Aspergillus flavus* and *Aspergillus parasiticus* are the most common species associated with aflatoxin contamination (Varga *et al.*, 2015; Lamothe, 2016). There are also the emerging mycotoxins such as fusaproliferin, moniliformin, beauvericin, and

enniatins produced mainly by *Fusarium* species; ergot alkaloids produced by *Claviceps*; and altenuene, alternariol, alternariol methyl ether, altertoxin, and tenuazonic acid produced by *Alternaria* species (Bottalico and Logrieco, 1998; Barkai-Golan and Paster, 2008; Marín *et al.*, 2013). These mycotoxins deserve particular attention since, currently, they are unregulated and were shown to occur frequently in agricultural products. The evidence of their incidence is rapidly increasing and gaps in toxicological knowledge have been identified for several compounds not allowing a proper risk assessment (Gruber-Dorninger *et al.*, 2017).

In addition to exposure through diet, humans, and animals can also be exposed to mycotoxins by inhalation of contaminated dusts in indoor and occupational settings where respirable particles below 1.0 µm may be present as particulate material that can act as carriers for mycotoxins (Straumfors *et al.*, 2014; De Santis *et al.*, 2019). In occupational settings, exposure can happen when organic dust containing mycotoxins is released during tasks such as storage work, loading, handling, or milling contaminated materials (grain, waste, and feed), and others such as caring for animals in animal husbandry settings (Viegas *et al.*, 2018). Additionally, transdermal studies have already proved that mycotoxins can penetrate through the skin, thus contributing for a health risk (Boonen *et al.*, 2012). These studies measured the kinetics of AFB₁, OTA, fumonisin B₁, citrinin, zearalenone and T-2 toxin and demonstrated that OTA have the highest permeation while AFB₁ the lower permeability rates (Boonen *et al.*, 2012). Moreover, in a study developed in poultry slaughterhouses intending to assess occupational exposure to AFB₁, it was shown that dermal route was probably responsible for the exposure found in the workers performing the poultry evisceration and the fact that workers were with their hands always in contact with water facilitated the dermal absorption (Viegas *et al.*, 2016).

The Usefulness of HBM in the Case of Mycotoxins Exposure Assessment

In the food safety approach, exposure assessment is conventionally performed combining consumption and occurrence data. However, it is well known that these methods are centered on some assumptions and uncertainties, even when probabilistic approaches are used. Considering the characteristics of HBM studies and type of data provided, it is possible to assume that exposure assessment performed through this direct approach contributes to overcome some of the limitations already identified such as the collection of consumption data, the heterogeneity of food contamination, the influence of culinary processing, and the interindividual variability (De Boevre *et al.*, 2013; Assunção *et al.*, 2016; de Nijs *et al.*, 2016; Zidek *et al.*, 2017; Martins *et al.*, 2019). In human biomonitoring studies of mycotoxins, it is important to include data collection on both food consumption and urine biomarkers, allowing simultaneously the identification of the main food contributors and validation of exposure, respectively (Martins *et al.*, 2020). As referred by Martins *et al.* (2020), the link between HBM data and food consumption data is more successful for mycotoxins with short half-lives because the moment of food survey are most of the times in accordance with urine sampling. Turner *et al.* (2008) compared data obtained for 24 h urine (urinary DON) with intake data from the UK National Diet and Nutrition Survey through a multiple linear regression model. Within this study it was possible to conclude that whole meal bread, pasta, fruit pies, buns/cakes, and white bread were contributors for exposure to DON and the respective increase in exposure when 50 g of each food were consumed (Turner *et al.*, 2008).

Recently, Viegas *et al.* (2018) extensively reviewed the available literature for occupational exposure to mycotoxins and the use of HBM to assess exposure (Viegas *et al.*, 2018). From this review, it was possible to conclude that the outputs of HBM studies conducted worldwide point out for the fact that mycotoxins can represent a risk in occupational settings (De Santis *et al.*, 2019). Furthermore, in recent studies developed in one industrial bakery and in swine farms the use of HBM allowed to recognize that even if workers are exposed through food consumption to mycotoxins, occupational exposure adds and contributes to the total exposure (Viegas *et al.*, 2018, 2019). In the same studies, HBM also revealed that exposure occurs as a mixture of mycotoxins, for both workers and general population. This is comprehensible since, besides the presence of multiple mycotoxins in the workplace environment, this is also a common feature of food commodities (Viegas *et al.*, 2019).

Overall, the use of HBM tools to assess exposure to mycotoxins in occupational context or by food consumption is an area of increasing research. Although many constraints still exist, the advances on knowledge of toxicokinetics of these compounds should be considered a step forward in this area. The HBM approaches to evaluate exposure to mycotoxins represent an adding value by providing more detailed information and making possible to understand exposure characteristics. Altogether, it will give support to risk management measures and policy actions, in order to reduce this exposure to the minimum possible.

Introduction

Mycotoxins are secondary metabolites produced by filamentous fungi and one of the most relevant group of food contaminants (Bennett and Klich, 2003). These toxins are considered ubiquitous and can affect the food chain in the stages of production, harvest, storage, and processing (Vettorazzi and López de Cerain, 2016). They are associated with several health outcomes in human and animal health such as, carcinogenic, immunotoxic, nephrotoxic, neurotoxic, teratogenic, and hepatotoxic effects (Wu *et al.*, 2014; De Ruyck *et al.*, 2015; Mally *et al.*, 2016; Ostry *et al.*, 2017) and constitute a concern from the public health and economic perspectives. To prevent these issues, many standards and regulation had been put in place (Eskola *et al.*, 2018, 2019).

Some mycotoxins have been pointed out as compounds presenting endocrine disruptive activity. According to the World Health Organization and the United Nations Environment Programme (UNEP), an endocrine disruptor (EDC) is a substance that alter one or more function of the endocrine system and consequently cause adverse effects in an intact organism, its progeny and a (sub)population (UNEP and WHO, 2012). EDCs may alter physiology during the whole life span of an individual, from fetal development to adult growth (Gore *et al.*, 2015), and with different degrees of evidence, could be associated to several health effects. These effects are also dependent on both the level and timing of exposure being especially critical when exposure occurs during development (UNEP and WHO, 2012).

Considering the human exposure through oral intake, EDCs are classified in four categories: EDCs with bioaccumulation ability (e.g., polychlorinated biphenyls – PCBs, polybrominated flame retardants, perfluorinated chemicals), compounds used for food production (e.g., pesticides), chemicals present in food due to contact materials (e.g., BPA), and endocrine-active substances naturally present in food (e.g., genistein; mycotoxins) (Diamanti-Kandarakis *et al.*, 2009; Ribeiro *et al.*, 2017).

The human exposure to EDCs is a public health concern and several attempts have been made in order to harmonize concepts and methodologies for hazard, safety, and risk assessment (EFSA, 2013; ECHA, EFSA and JRC, 2018).

Considering that endocrine-active substances naturally present in food as mycotoxins constitute an emerging threat to public health and the recent data evidencing human exposure to these compounds, here the authors intend to gather and systematize key information regarding mycotoxins considered EDCs.

Zearalenone

Main Characteristics

The *Fusarium* mycotoxin ZEN, considered the parent compound, belongs to a family of compounds sharing the ring system of a macrocyclic β -resorcylic acid lactone (RAL). It is produced by *Fusarium* species such as *F. graminearum*, *F. culmorum*, *F. equiseti*, and *F. verticillioides* (Steinkellner *et al.*, 2019). Modified forms of ZEN have been described mainly in food from plant origin, due to the biotransformation performed by plants and/or fungi (EFSA, 2016). These compounds formed by conjugation with sulfate (ZEN-Sulf) and glucose (ZEN-Glc) molecules are important because they are hardly detected by the routine food analysis (Rychlik *et al.*, 2014).

Zearalenone is stable, does not degrade at high temperature and exhibits fluorescence under ultraviolet (UV) light. The structure and shape of zearalenone and its metabolites resembles endogenous estrogen, the 17 β -estradiol (Kowalska *et al.*, 2016).

Metabolism of Zearalenone

Following ingestion and absorption, ZEN is metabolized mainly by enterocytes and hepatocytes (Molina-Molina *et al.*, 2014). The biotransformation of ZEN occurs in two major pathways. The phase I is characterized by the reduction of the keto group to an alcoholic hydroxyl group to yield the stereoisomeric compounds α -zearalenol (α -ZEL) and β -zearalenone (β -ZEL). Reduction of the olefinic double bond of ZEN leads to zearalanone (ZAN), and reduction of both the olefinic double bond and keto group to α -zearalanol (α -ZAL) and β -zearalanol (β -ZAL) (Steinkellner *et al.*, 2019). The phase II is characterized by the conjugation of the parent compound and/or the phase I metabolites with glucuronides or sulfate groups in order to become polar and facilitate the urinary excretion. The conjugated metabolites are excreted in the bile and entero-hepatic recirculation and finally eliminated with urine (Molina-Molina *et al.*, 2014). Fitzpatrick *et al.* (1988) analyzed the metabolism of ZEN and found α -ZEL to be the major

Table 1 Relative potency factors for ZEN, metabolites, and modified forms as defined by EFSA

Compound	Relative potency factor
β -ZEL; β -ZEL-Glc, β -ZEL-Sulf	0.2
ZEN, ZEN-Glc, ZEN-Sulf, cis-ZEN, cis-ZEN-Glc, cis-ZEN-Sulf, cis- β -ZEL, cis- β -ZEL-Glc, cis- β -ZEL-Sulf	1.0
ZAN, ZAN-Glc, ZAN-Sulf	1.5
β -ZAL, β -ZAL-Glc, β -ZAL-Sulf	2.0
α -ZAL, α -ZAL-Glc, α -ZAL-Sulf	4.0
cis- α -ZAL, cis- α -ZAL-Glc, cis- α -ZAL-Sulf	8.0
α -ZEL, α -ZEL-Glc, α -ZEL-Sulf	60

Abbreviations: cis-ZEN, cis-zearelanone; cis-ZEN-Sulf, cis-zearelanone-sulfate; cis- β -ZEL, cis- β -zearelanol; cis- β -ZEL-Glc, cis- β -zearelanol-glucoside; cis- β -ZEL-Sulf, cis- β -zearelanol-sulfate; cis- α -ZAL, cis- α -zearelanol; cis- α -ZAL-Glc, cis- α -zearelanol-glucoside; cis- α -ZAL-Sulf, cis- α -zearelanol-sulfate; ZAN, zearelanone; ZAN-Glc, zearelanone-glucoside; ZAN-Sulf, zearelanone-sulfate; ZEN, zearelanone; ZEN-Glc, zearelanone-glucoside; ZEN-Sulf, zearelanone-sulfate; β -ZEL, β -zearelanol; β -ZEL-Glc, β -zearelanol-glucoside; β -ZEL-Sulf, β -zearelanol-sulfate; β -ZAL, β -zearelanol; β -ZAL-Glc, β -zearelanol-glucoside; β -ZAL-Sulf, β -zearelanol-sulfate; α -ZAL, α -zearelanol; α -ZAL-Glc, α -zearelanol-glucoside; α -ZAL-Sulf, α -zearelanol-sulfate; α -ZEL, α -zearelanol; α -ZEL-Glc, α -zearelanol-glucoside; α -ZEL-Sulf, α -zearelanol-sulfate.

Note: EFSA, 2016. Appropriateness to set a group health-based guidance value for zearelanone and its modified forms. EFSA Journal 14 (4). doi:10.2903/j.efsa.2016.4425.

metabolite in the feces and the conjugated glucuronides to be the major metabolites in the urine (Fitzpatrick *et al.*, 1988). The extents and rates of various metabolic reactions are important because the metabolites of ZEN vary in their estrogenic potential (Mukherjee *et al.*, 2014).

Recently, Slobodchikova *et al.* (2019) performed an experiment to generate phase I and phase II (glucuronidation) metabolites of mycotoxins (including ZEN) using standard *in vitro* microsomal incubation protocol. Regarding ZEN, for phase I there were reported a variety of ZEN oxidized metabolites and for phase II the glucuronidation pathway was confirmed as the predominant metabolic pathway. Phase II reactions resulted in various glucuronide forms of parent toxin, its metabolites of phase I reactions and double glucuronide forms (Slobodchikova *et al.*, 2019).

Mode of Action and Toxicity

The human exposure to ZEN is not associated with acute episodes. However, the chronic exposure is of potential concern due to the structural similarity of ZEN with 17 β -estradiol. This characteristic allows the binding of ZEN to estrogen receptors with high binding affinity and thereby exerting estrogenic effects (Mally *et al.*, 2016).

Regarding the estrogenic activity of ZEN, metabolites and modified forms, an important aspect is the establishment of the relative potency factors for each compound. Overall, the limited number of studies using the uterotrophic effect as endpoint for estrogenicity showed that phase I metabolites of ZEN retain estrogenic activity. The α -isomers are invariably much more estrogenic than the corresponding β -isomers, and exceed the estrogenicity of ZEN. The orientation of the hydroxyl group at the aliphatic ring proved to have a pronounced effect on the estrogenic activity, with α -ZEL being more estrogenic than β -ZEL and ZEN (Metzler *et al.*, 2010). The estrogenic potency of α -ZEL *in vivo* is about 62 times higher than ZEN and one order of magnitude lower than that of the most potent endogenous estrogen 17 β -estradiol (EFSA, 2016). Reduction of the olefinic double bond of ZEN, leading to ZAN, virtually does not change the hormonal activity (EFSA, 2016). The EFSA CONTAM Panel proposed relative potency factors based on the relative estrogenicity potencies determined in the uterotrophic assay and given on a molar basis (Table 1).

In 2011, the EFSA CONTAM Panel identified the estrogenic activity of ZEN as the critical effect with female pigs being the most sensitive to this effect. Based on a No Observed Effect Level (NOEL) in pigs of 10.4 $\mu\text{g kg}^{-1} \text{ bw day}^{-1}$ and considering an uncertainty factor of 40 (4 for interspecies differences in toxicokinetics because humans were considered not to be more sensitive than the female pig, and 10 for intra-human variability), a TDI of 0.250 $\mu\text{g kg}^{-1} \text{ bw day}^{-1}$ was established (EFSA, 2011). In 2016, the EFSA CONTAM Panel considered the effects of ZEN, its metabolites and modified forms as additive and proposed a group TDI for all these related compounds of 0.250 $\mu\text{g kg}^{-1} \text{ bw day}^{-1}$ (EFSA, 2016).

The mechanisms by which ZEN influences the synthesis and secretion of mammalian sex steroid hormones were recently reviewed by Zheng *et al.* (2019) and Rai *et al.* (2019). These mechanisms include: Interference in feedback that mediate FSH and LH production in pituitary gland, the inhibition of viability of Leydig and granulosa cells that produce sex steroids, the oxidative stress by stimulating the leakage of electrons and increasing the levels of free radicals, the induction of cell apoptosis, and the influence on mitochondrial functions (Rai *et al.*, 2019; Zheng *et al.*, 2019).

Due to its ability to induce cell proliferation, some studies assessing the carcinogenicity of ZEN have been performed. The experimental studies were performed in animals with results showing induction of hepatocarcinoma (mice), prostate gland inflammation, mammary gland cysts, and increased hepatocellular vacuolization (rats) (NTP, 1982). Regarding studies in humans, scarce data are available. Belhassen *et al.* (2015) found a potential correlation between development of breast cancer and exposure to ZEN by obtaining results (adjusted OR = 1.54, 95% CI = 1.10–2.77) that suggested a potential role of α -ZAL in the risk of developing breast cancer. However, the data available is limited and further assessments should be performed. Due to lack of evidence regarding the carcinogenic effect of ZEN, it is classified in group 3 of IARC (not classifiable up to its carcinogenicity to humans) (IARC, 1993).

Another recent issue is the transfer of contaminants through placental barrier and consequently the early-life exposure to these substances. Recently Warth *et al.* (2019) performed an *ex vivo* experiment and obtained results suggested that there is *in utero* exposure to ZEN, α -ZEL, and ZEN-14-sulf. These results highlighted the need for further assessments regarding the early-life exposure.

Occurrence of Zearalenone in Food

ZEN is produced by fungi of the genus *Fusarium*, which attacks crops during its growth in the field as well as during storage period. Humans can be exposed to ZEN directly, by contaminated food, or indirectly, through products derived from animals exposed to mycotoxins (Marin *et al.*, 2013). ZEN production is favored by high humidity and low temperature conditions and it simultaneously occurs with deoxynivalenol and less frequently with aflatoxins (Alshannaq and Yu, 2017), thus contributing for the issue of co-occurrence of mycotoxins (Alassane-Kpembé *et al.*, 2016).

ZEN is not removed during processing and affects the entire human food chain through a range of food products including cereals, meat, milk, wine, beer, dried fruits, and spices (De Boevre *et al.*, 2013; Nathanail *et al.*, 2015; Ribeiro *et al.*, 2015; Abrunhosa *et al.*, 2016; Lee and Ryu, 2017).

Considering the health effects associated to human exposure to ZEN, and aiming to protect the consumers' health, the European Commission established maximum admissible levels for the occurrence of ZEN in foods. These levels are laid down in Regulation 1881/2006 and ranged from 20 to 200 $\mu\text{g kg}^{-1}$ (European Commission, 2006a), according to the considered food matrix. Considering the possibility of human indirect exposure and the economic burden, the European Commission produced a recommendation of guidance levels for the occurrence of ZEN in feed, ranging from 100 to 3000 $\mu\text{g kg}^{-1}$ (European Commission, 2006b). In China, the ML for ZEN has been regulated at 60 $\mu\text{g kg}^{-1}$ in wheat, wheat flour, corn, and corn flour (NHC and CFDA, 2017). In USA there are no maximum admissible levels established for the occurrence of ZEN in food and feed.

Alternaria Toxins

Main Characteristics

Alternaria fungi, where the most predominant is *A. alternata*, are a common plant pest in cereals, oilseeds, fruits, and vegetables (Arcella *et al.*, 2016). *Alternaria* fungi do not only contaminate harvests they can also spoil foods in the fridge-temperatures. *Alternaria* species produce more than 70 phytotoxins and some of them have been chemically characterized as mycotoxins to humans and animals. These metabolites can be grouped into several categories and seven main different groups exist: Nitrogen-containing compounds, steroids, terpenoids, pyranones, quinones, phenolics, and others (Lou *et al.*, 2013) (Fig. 1).

The group of pyranones is the most studied because important mycotoxins as alternaric acid (AltA), alternariol (AOH), alternariol monomethyl ether (AME), and altenuene (ALT) are included in this group. Few dibenzopyranones (two benzene rings) are produced by *Alternaria* fungi but they are the most important toxic compounds because AOH and AME are included in this group.

Nitrogen-containing metabolites are classified in three different groups: amines and amides, cyclopeptides, and other nitrogen-containing metabolites. Important *Alternaria* mycotoxins as tenuazonic acid (TeA) and altersetin are classified as amines and amides. Tenuazonic acid is considered the most acute toxic *Alternaria* mycotoxin (Asam and Rychlik, 2013). Altersetin toxicity has not been widely studied, but its presence caused the inhibition of topoisomerase II human cells (Jarolim *et al.*, 2017).

Quinones are derived from aromatic compounds as benzene or naphthalene resulting in a fully conjugated cyclic dione structure. Two different quinones groups are produced by *Alternaria*: Anthraquinones and perylenequinones. Macrosporin A and altersolanol A are considered the most important anthraquinones because of their presence in food and toxicity. Macrosporin A can be commonly found in food products; for instance 79% of wheat samples analyzed in Nigeria (Egbontan *et al.*, 2017) and 57% of the analyzed nuts samples were positive for macrosporin A occurrence (Varga *et al.*, 2013). Perylenequinones are characterized by a pentacyclic-conjugated chromophore. Large amount of perylenequinones are produced by *Alternaria* genera and some of them can be toxic. The most important toxic perylenequinones compounds produced by *Alternaria* are Altertoxin (I, II, and III), alterperyleneol and stemphytoxin (I, II, and III). They are less common than anthraquinones but they are the *Alternaria* toxins with the strongest mutagenic properties (Fleck *et al.*, 2012, 2016). However, there are a lack of data about perylenequinones presence in food and it is not clear if these mycotoxins may be a concern for public or animal health.

Phenolic metabolites from *Alternaria* fungi have phenolic group in the structure. Up to now, toxic phenolic compounds for humans or animals produced by *Alternaria* fungi have not been identified. Resveratrol can be produced by some *Alternaria* species and it can reduce the risk of some human diseases as cancer and cardiovascular disease (Shi *et al.*, 2013).

Mode of Action and Toxicity

The most important *Alternaria* mycotoxins due to their harmful effects are alternariol (AOH), alternariol monomethyl ether (AME), tenuazonic acid (TeA), altenuene (ALT), tentoxin (TEN), and alter toxins (ATX) (Ostry, 2008). *Alternaria* mycotoxins are well known to have estrogenic activity, however, this will be always lower than ZEN estrogenic activity (Dellafiora *et al.*, 2018).

Fig. 1 Classification of *Alternaria* metabolites with the most important mycotoxins for each group.

Some *Alternaria* mycotoxins and several phase I and II metabolites of them are able to bind and activate estrogen receptors (ER) because they act as mimetic of 17- β -estradiol (Lehmann *et al.*, 2006; Dellafiora *et al.*, 2018), and AME has the strongest estrogenic activity (Dellafiora, Dall'Asta and Galaverna, 2018). For instance, AOH replaced estradiol from isolated recombinant ER- α and - β , acting as pure ER agonist. The AOH affinity was approximately 10,000 and 2500 times less than the endogenous hormone 17 β -estradiol for the ER- α and ER- β , respectively (Frizzell *et al.*, 2013). *Alternaria* causes the increase of progesterone receptor expression as a synergistic effect of *Alternaria* estrogenic potency, so, hormone levels can be affected due to the *Alternaria* presence. Thus, an increase of progesterone and estradiol production was detected after cells were exposed to AOH. On the other hand, testosterone and cortisol were not affected. Some *in vitro* studies concluded that *Alternaria* toxins exert genotoxic, mutagenic, and carcinogenic properties. Thus, AOH and AME induced DNA strand breaks at concentrations $\geq 1 \mu\text{M}$ and had mutagenic potential at $\geq 10 \mu\text{M}$ (Brugger *et al.*, 2006; Fehr *et al.*, 2009). AOH and AME are also cytotoxic because human intestinal cells viability (HCT 116 and Caco-2) were reduced after exposure to AOH and AME. For cells viability, the synergistic effect of AOH and AME was again observed because the toxic effect was higher when both mycotoxins were present (Bensassi *et al.*, 2015; Fernández-Blanco *et al.*, 2016). The carcinogenic effects of *Alternaria* toxins has not been tested in *in vivo* studies; however, *Alternaria* mycotoxins were believed to be one of the causes of human esophageal cancer (Zhen *et al.*, 1991). Hence, due to their possible harmful effects, *Alternaria* toxins are of concern for public health.

Although *Alternaria* toxins have a significant toxicity, relevant *in vivo* toxicological data are not available and consequently an appropriate risk assessment is still lacking. Additionally, the co-occurrence of *Alternaria* mycotoxins with other mycotoxins that could cause a synergistic toxic effect is a possible scenario, as it was observed for AOH and ZEN in an *in vitro* study (Crudo *et al.*, 2019).

Occurrence of *Alternaria* Toxins in Food

The presence of *Alternaria* toxins in food has not been widely studied as other mycotoxins. However, the interest of *Alternaria* presence in food products increased and several studies showed that *Alternaria* toxins are common in food (Escrivá *et al.*, 2017). Cereals, vegetables, fruits, grains, and wine are the food items where the occurrence of *Alternaria* toxins is reported (Aichinger *et al.*, 2019). The frequent co-occurrence of multiple *Alternaria* toxins was also described in many other foods, including peppers. As an example, (Gambacorta *et al.*, 2019) analyzed samples of fresh, dried, grounded, and fried sweet pepper, wherein AOH, AME, TeA, and TEN were found together (limit of quantifications in the low $\mu\text{g kg}^{-1}$ range). In particular, TeA was detected in all samples, while AOH was detected in 86%, 43%, 100%, and 14% of fresh, dried, grounded, and fried products, respectively.

AOH and AME are frequently found in combination (Vaquera *et al.*, 2016) as they share a common biosynthesis pathway (Saha *et al.*, 2012). Due to its large presence in food products, EFSA did a dietary exposure assessment for AOH, AME, TeA, and TEN to the European population using 15,563 analytical results from 4249 selected samples (Arcella *et al.*, 2016). The highest mean levels of AOH were reported for some grains in particular for buckwheat and oats. AOH was also present in diverse samples of tomato-based products such as tomato puree and tomato sauce. The presence of AME was lower and its highest occurrence was found in samples of tree nuts and oil seeds, in particular chestnuts and sesame seeds. TeA was reported in high concentrations in samples of tomatoes and several tomato-based products and an average concentration of $351.2 \mu\text{g kg}^{-1}$ was found in tomato soup (dried soup) (Arcella *et al.*, 2016). EFSA assessed the dietary exposure from all the analytical data gathered and toddlers and children presented the highest dietary exposure to *Alternaria* mycotoxins. Considering the upper-bound approach results, toddlers and infants presented a mean exposure of 1614 and $1490 \text{ ng kg}^{-1} \text{ bw day}^{-1}$ to TeA, 71.6 and $54.4 \text{ ng kg}^{-1} \text{ bw day}^{-1}$ to AOH, 38.8 and $34.4 \text{ ng kg}^{-1} \text{ bw day}^{-1}$ to AME, 33.4 and $30.1 \text{ ng kg}^{-1} \text{ bw day}^{-1}$ to TEN, respectively. Cereal-based food for infants and young children was considered the main contributor to the high dietary exposure to TeA (Arcella *et al.*, 2016).

Although *Alternaria* toxins are common in food samples, currently there is not any regulation for the occurrence in food and feed in any region of the world. As *Alternaria* metabolites are toxic compounds and they are common in food, a regulation to establish maximum admissible limits should be established in the coming years.

Metabolism of *Alternaria* Toxins

As *Alternaria* toxins group is formed by highly diverse chemical structures, it is also difficult to predict a similar metabolism pattern for all of them. Contrary to other mycotoxins, scarce information exists about *Alternaria* mycotoxins metabolism. *In vitro* and *in vivo* studies agreed that AOH and AME are hydroxylated at various positions. AME was metabolized to six different compounds (dihydroxy-AME, 8-hydroxy-AME, 10-hydroxy-AME, 4-hydroxy-AME, 2-hydroxy-AME, methyl-hydroxy-AME) while AOH was metabolized to five different hydroxyl compounds (8-hydroxy-AOH, 4-hydroxy-AOH, 10-hydroxy-AOH, 2-hydroxy-AOH, and methyl-hydroxy-AOH) (Pfeiffer *et al.*, 2007). *In vitro* studies performed with rat and human cell livers from phase I caused the apparition of four different hydroxylated altenuene compounds (8-hydroxy-altenuene, 10-hydroxy-altenuene, 4-hydroxy-altenuene, and stereoisomer of 4-hydroxy-altenuene). Moreover, 8-hydroxy-altenuene was identified as the predominant metabolite while the other three metabolites (10-hydroxy-altenuene, 4-hydroxy-altenuene, and stereoisomer of 4-hydroxy-altenuene) were formed in much smaller amounts (Pfeiffer *et al.*, 2009). All the studied species followed a similar pattern, with 8-hydroxy-altenuene appearing as the predominant compound. Phase II metabolism led to the formation of glucuronide metabolites and > 75% of 8-hydroxy-altenuene was conjugated to glucuronide acid (Pfeiffer *et al.*, 2009). Apparently, human fecal microbiota is not able to metabolize AOH, AME, and ALT (Lemke *et al.*, 2016).

Alternaria mycotoxins can be metabolized to several other compounds and some of them could be the predominant in biological fluids. However, metabolite compounds have not been analyzed *in vivo* samples. There is a need to check the metabolism of *Alternaria* mycotoxins *in vivo* samples to perform a correct biomonitoring program.

Biomonitoring and Toxicokinetic Studies

Although traditionally performed combining consumption and occurrence data, the use of this method to assess human exposure could be associated to some uncertainties that a biomonitoring approach could solve. Over the last years, biomonitoring has been considered a powerful and promising tool to assess the exposure to contaminants. Traditional biomonitoring studies of internal exposure through urine or plasma analysis of targeted chemicals or metabolites are useful to link exposures to health outcomes. There are still some gaps to be able to link the mycotoxin intake with the mycotoxin concentration analyzed in the biological fluids. To solve these gaps, it is necessary to unravel the mycotoxin metabolism and the toxicokinetics (Vidal *et al.*, 2018).

In recent years, several studies tried to develop toxicokinetics models in humans for different mycotoxins, and ZEN and *Alternaria* mycotoxins have not been an exception. For ZEN, there was a first study performed with only one adult volunteer (Mirocha *et al.*, 1981). ZEN was administrated by oral dose (100 mg) and the urine was collected during 24 h and analyzed

Table 2 Presence of zearalenone and its metabolites in the biological samples analyzed from 2015 to 2019

Matrix	Mycotoxins	N (%)	LOD (ng mL ⁻¹)	Average conc. (ng mL ⁻¹)	Max. Conc. (ng mL ⁻¹)	Average conc. (ng g ⁻¹ creatinine)	Max. Conc. (ng g ⁻¹ creatinine)	Country	Reference

^aUrine samples collected during 24 h.

by ZEN, α -ZEL, β -ZEL. The urine analysis showed that it was not possible to detect ZEN, α -ZEL, β -ZEL without a previous β -glucuronidase treatment. After β -glucuronidase treatment, ZEN ($13.27 \mu\text{g mL}^{-1}$) followed by α -ZEL ($12.94 \mu\text{g mL}^{-1}$) were the predominant compounds found in urine. β -ZEL was also detected ($4.63 \mu\text{g mL}^{-1}$). However, since ZEN, α -ZEL, and β -ZEL were detected after β -glucuronidase treatment, it means that all detected forms were in the glucuronide form. The urine samples were gathered at three different times (6, 12, and 24 h). All three compounds showed a similar excretion pattern with lower concentrations in the first 6 h after ZEN administration, $3.71 \mu\text{g mL}^{-1}$ (ZEN) and $2.97 \mu\text{g mL}^{-1}$ (α -ZEL), without detection of β -ZEL. The second period of collection (from 6 to 12 h after oral administration) achieved the highest rate of mycotoxin extraction for all three analyzed mycotoxins: $6.87 \mu\text{g mL}^{-1}$ of ZEN, $6.00 \mu\text{g mL}^{-1}$ of α -ZEL, and $2.66 \mu\text{g mL}^{-1}$ of β -ZEL. Finally, from 12 to 24 h after ZEN administration, the concentration recovered started to decrease $2.69 \mu\text{g mL}^{-1}$ of ZEN, $4.02 \mu\text{g mL}^{-1}$ of α -ZEL, and $1.97 \mu\text{g mL}^{-1}$ of β -ZEL. The glucuronide forms present in the analyzed urines could be ZEN-14-glucuronide, ZEN-16-glucuronide, ZEN-14,16-diglucuronide, α -ZEL-14-glucuronide, and β -ZEL-14-glucuronide. Another toxicokinetic study of ZEN was performed using only one volunteer again (Warth *et al.*, 2013). They monitored urinary excretion of ZEN after the unique volunteer was exposed to ZEN at a dose of $0.167 \mu\text{g kg}^{-1} \text{ bw}$ via a naturally contaminated diet for four consecutive days. Following enzymatic hydrolysis, the concentration of total ZEN (as the sum of conjugated and unconjugated ZEN) was measured in 24-h urine samples collected before, during and after ZEN exposure. ZEN was reported to be present mainly in the form of its glucuronide (ZEN-14-glucuronide). During ZEN exposure, concentration of total ZEN in 24-h urine samples ranged from 0.30 to 0.59 ng mL^{-1} , which corresponded to an excretion rate of 7.0% – 13.2% of the administered dose within 24 h. Other metabolites such as α -ZEL and β -ZEL were not analyzed (Warth *et al.*, 2013). From the few existing information about ZEN toxicokinetics in humans, it seems clear that glucuronides forms of ZEN and α -ZEL are the predominant compounds in the urine (Martins *et al.*, 2019). The predominance of glucuronides form of ZEN and α -ZEL agrees with the *in vitro* results.

Recent years, several studies analyzed ZEN and its metabolites in biological fluids (Table 2). *In vitro* studies have been able to detect more than 30 different ZEN metabolites (Yang *et al.*, 2017). There are mainly products from hydroxylation, reduction, and glucuronidation but they are only small fraction of total ZEN excretion. The metabolites α -ZEL, β -ZEL 8-OH-ZEN, 15-OH-ZEN, and ZEN-14-glucuronide are the predominant forms *in vitro*. In addition, ZEN, α -ZEL, and β -ZEL can be mutually transformed in liver microsomes. Although ZEN is metabolized to an amalgam of ZEN forms, biomarker-analysis in urine should focus on free ZEN, α -ZEL, β -ZEL, and some of the most common hydroxylation and glucuronidation products like 8-OH-ZEN, 13-OH-ZEN, 15-OH-ZEN, and ZEN-14-glucuronide (Vidal *et al.*, 2018).

ZEN, α -ZEL, and β -ZEL and their glucuronide forms are the most analyzed metabolites in biological samples and these are the predominant compounds in urine. Thus, (Martins *et al.*, 2019) who analyzed the major quantity of ZEN metabolites in urine (10 different compounds, Table 2), found only presence of ZEN, ZEN-14-glucuronide and α -ZEL. Other studies found presence of other ZEN compounds; however, their concentrations were normally low and with small percentage of positive samples.

Few toxicokinetics with *Alternaria* mycotoxins have been performed. Moreover, as *Alternaria* mycotoxins are structurally very different among them, the results cannot be compared. Firstly, important differences in absorbance have been detected among *Alternaria* mycotoxins. Therefore, AOH and AME had a low systemic absorption and they were mainly excreted by feces ($>85\%$) and they were scarcely recovered in the urine ($<10\%$) after 24 h of oral administration in rats (Schuchardt *et al.*, 2014; Puntischer *et al.*, 2019). It is recommended to non-target analysis of AOH and AME metabolites in blood and urine to perform biomonitoring of AOH or to study its metabolism. The low absorption of AOH and AME points out that they should be found in feces, moreover, they could be in free form because apparently human fecal microbiota is not able to metabolize AOH and AME (Lemke *et al.*, 2016). Šarkanj *et al.* (2018) detected for the first time AOH in human urine samples: 6.7% of analyzed samples ($n=120$) from Nigeria were positive for AOH with an average concentration of 0.06 ng mL^{-1} (Šarkanj *et al.*, 2018). Martins *et al.* (2019) detected AOH in 29% ($n=94$) of the analyzed Portuguese samples, with a median concentration of 0.28 ng mL^{-1} . The larger AOH detection in Portuguese samples may be due to collection of 24-h urine samples (Martins *et al.*, 2019). Future biomonitoring studies should focus on hydroxylated and glucuronide metabolites, specially, phase II metabolites that could be the expected predominant compounds (Pfeiffer *et al.*, 2009).

TeA has a higher percentage of absorption; in a study performed with two human volunteers, $>87\%$ of orally administered TeA was recovered in the free form in urine within 24 h (Asam *et al.*, 2013). As TeA is mainly excreted in free form in the urine, it was detected in two different studies were human urine samples from Germany were analyzed (Table 3). All the analyzed samples were positive for TeA presence (Asam *et al.*, 2013; Hövelmann *et al.*, 2016).

Therefore, apart from AOH and AME, other *Alternaria* mycotoxins as TeA and STX should be included in the biomonitoring programs due to their large presence and toxicity. However, elucidating the toxicokinetics is necessary for all *Alternaria* mycotoxins to perform an accurate biomonitoring program.

There is a clear need for further validation of ZEN and *Alternaria* toxins and their metabolites as urinary biomarkers of mycotoxins exposure by determining urinary excretion rates in a larger number of individuals to take into account possible inter-individual differences caused by different factors as gender and age.

Conclusions and Future Perspectives

Considering the available reviewed literature, it is important to highlight the adverse health effects that exposure to *Alternaria* mycotoxins and zearalenone may pose to human health. The estrogenic effects are a major concern particularly in early-life and

pre-pubertal stages of development; however, the effects of both mycotoxins go far beyond and possible cytotoxic, immunotoxic, and carcinogenic effects are attributed to these mycotoxins. Several gaps are identified; the knowledge on toxicokinetics of both mycotoxins is still very incomplete and the development of future studies to unravel the metabolism in human body is of high importance. A more complete information on metabolism makes possible not only the use of biomonitoring tools to accurately assess the exposure but also a proper risk assessment. Additionally, the interaction of mycoestrogens with other potential EDCs from other sources should be assessed in order to have a deeper knowledge on the burden related with the exposure to these compounds, supporting the establishment of preventive measures that ensure public health.

Fungi in Milk and in Dairy Products

Karolina Rópejko, Jan Grajewski, and Magdalena Twarużek, Kazimierz Wielki University, Bydgoszcz, Poland

© 2021 Elsevier Inc. All rights reserved.

Introduction

Fungi are commonly found in the environment. They are eukaryotic, gram-positive, heterophilic living microbes (Pal, 2014). They are carcinogenic, cytotoxic, neurotoxic, immunosuppressive, they can cause allergic reactions and “sick building syndrome – SBS”. The most popular fungi found in food are species of the genus *Aspergillus* (*A. ochraceus*) – cereals, peanuts, coffee beans; *Penicillium* (*P. expansum*, *P. notanum*, *P. chrysogenum*, *P. cyclopium*) – stale bread, cheese, apples, citrus; *Fusarium* (*F. poae*, *F. graminearum*, *F. sorotrichoides*, *F. oxysporum*, *F. solani*) – cereals and crops (Chróst, 2016). (Tables 1 and 2).

Also from the medical perspective, reduction of the fungi occurrence in foods is important – fungi can produce mycotoxins that are toxic to humans – they are hepatotoxic, nephrotoxic, neurotoxic, teratogenic, estrogenic, have immunosuppressive effects, can damage the digestive system, can cause cancer and reproductive problems.

The main reason of products contamination by fungi are a warm climate and inadequate cooling (Pal, 2014). Contamination of products by fungi can also come from air, surfaces, ingredients and environment. Fungi contamination can be visible in the form of colonies or so-called “toad skin” or “cat hair”. This is caused by fungi of the genera *Galactomyces geotrichum* and *Mucor* spp. (Garnier et al., 2017b).

Some of the researches estimate that 5%–10% of all produced food in the world is lost because its spoilage by fungi (Buehler et al., 2017; Garnier et al., 2017a; Buehler et al., 2018).

Milk and dairy products are a major type in few diets habits in many countries, therefore is very important to monitor and protect these products from contamination (Bouillon et al., 2019).

Table 1 Fungi and mycotoxins which they can produce

Table 2 Maximum levels of mycotoxins in milk and dairy products

Mycotoxins	Milk and milk products	maximum levels [$\mu\text{g/kg}$]
Aflatoxin M ₁	Raw milk, heat-treated milk and milk for the manufacture of milk-based products	0.05
	Infant formulas and follow-on formulas, including infant milk and subsequent milk	0.025
Ochratoxin A	Dietary products for children (e.g., milk)	0.5

Note: (EC) No 1881/2006, 2006. Commission Regulation (EC) No 1881/2006 of 19 December 2006 Setting Maximum Levels for Certain Contaminants in Foodstuff.

Fungi and Yeasts in Milk

Milk for human consumption is most commonly derived from cows – almost 83% of world milk production (Pal, 2014; Becker-Algeri *et al.*, 2016; Conte and Panebianco, 2019), but milk can be also obtained from a variety of animal sources such as goat (2%), sheep (1%) and buffalo (13%) (Becker-Algeri *et al.*, 2016), donkey (less than 0.1% and it is used as a substitute of breastmilk) (Sarno *et al.*, 2012; Conte and Panebianco, 2019) and human for human consumption. Cow's milk can be consumed directly as well as a component of dairy products and milk powder. Goat milk has been gaining benefits as an alternative to cow's milk, because it is less likely to cause allergies. It has also higher levels of iron and fat content. A soft curd is formed with it, which is more digestible. Cheeses made from goat's milk are popular in the Mediterranean and southern regions of Europe (Quigley *et al.*, 2013).

Sheep's milk is rarely drinking raw, and it is often used to make sheep's cheese (Quigley *et al.*, 2013; Spanamberg *et al.*, 2014).

Buffalo milk is consumed mostly in India and Pakistan. It is not common in Europe, but it is important in some Mediterranean countries, where it is utilized for making a traditional mozzarella cheese (Quigley *et al.*, 2013).

In the countries of the Mediterranean region, donkey milk and products based on it are very popular. It has low fat and protein content, while high lactose content (Malissiova *et al.*, 2015; Gross *et al.*, 2019).

Raw milk is very good environmental medium for the fungal growth, because it has a specific composition: it contains proteins, carbohydrates, minerals, fat and vitamins (Lawan *et al.*, 2012; Elhaj *et al.*, 2014). Microbial contamination of milk and milk products is mostly caused by unhygienic conditions, human factors, air, surfaces, supplier ingredients and milking environment on a farm (Cooke and Brazis, 1968; Pal, 2014; Garnier *et al.*, 2017b; Buehler *et al.*, 2018). Fungi are also commonly found in the dairy farms, therefore they can be present as a natural contaminants in raw milk. However this kind of fungi are mostly heat sensitive, thus they are not a direct source of fungi contamination in dairy products made of them (Buehler *et al.*, 2017). Raw milk contains a lot of nutrients for people in any age (especially it is consumed by infants and in childhood), however it has a neutral pH and high water content, which enables the growth and development of many microorganisms including fungal species (Vahedi *et al.*, 2013; Gulbe and Valdovska, 2014; Amaechi and Adiele, 2015; Von Neubeck *et al.*, 2015; Becker-Algeri *et al.*, 2016).

In addition, the occurrence of fungi in raw milk is affected by physiological condition of animals, breeding conditions and even the weather (Delavenne *et al.*, 2011; Quigley *et al.*, 2013). The presence of fungi is also affected by certain climate and vegetation features, as well as geographical location (Pešić-Mikulec *et al.*, 2005).

Additionally, dairy cattle suffer for mastitis, which can be caused by yeast like *Candida* spp. This is an inflammatory reaction of the udder. This infections are really common and also the most costly disease in dairy industry. Milk from cows with these infections has higher somatic cell count lowering the quality of milk. As a result, milk originating from the dairy cattle suffering from mastitis is not marketable (Dworecka-Kaszak *et al.*, 2012), since can contain flakes, clots, blood or has another color (Zastempowska *et al.*, 2016). Environmental factors have an important influence on fungal growth. Although there are some species that grow in specific seasons and in particular conditions, they have also a capability of living for the whole year (Pešić-Mikulec *et al.*, 2005). Also microbiota of milk can vary from other milk farms (Lavoie *et al.*, 2012).

Due to fungal contamination milk mycotoxins can be also present. Many studies indicate the presence of zearalenone in cow's milk (Gajęcka and Gajęcki, 2014; Becker-Algeri *et al.*, 2016), in bovine milk (Becker-Algeri *et al.*, 2016), in ruminants' milk (Zastempowska *et al.*, 2016), aflatoxin M₁ in cow's milk (Pitt, 2000; Sengun *et al.*, 2008; Jankovic *et al.*, 2009; Becker-Algeri *et al.*, 2016; Decontardi *et al.*, 2018), in bovine milk (Becker-Algeri *et al.*, 2016), in human breast milk (Sengun *et al.*, 2008; Zastempowska *et al.*, 2016) and fumonisins in bovine and human milk (Zastempowska *et al.*, 2016). (Table 3).

Fungi and Yeasts in Dairy Products

Dairy products are products derived from processed milk. It is consumed every day by millions people in the world, so the risk of a potential food-borne contamination is a big concern for people (Lawan *et al.*, 2012).

As a result of milk fermentation by bacteria, yeast or fungi can produce many products such as cheese, butter or yogurts (Moreira *et al.*, 2001). However, also the contamination of milk can have an influence to the physical and organoleptic characteristics of milk. On the other hand, characteristics of milk may affect the quality and shelf life of dairy products (Spanamberg *et al.*, 2014). Therefore, contamination of milk has an impact on the contamination of dairy products made of it.

Kefir is a symbiotic combination of microorganisms – lactic acid bacteria, yeast, sometimes acetic acid bacteria along with natural polysaccharides and protein matrix. Kefir grains are elastic, slimy, white to pale yellow with irregular structure, usually

1–3 cm long (Garofalo *et al.*, 2015; Bengoa *et al.*, 2018). Research conducted by Garofalo *et al.* in Italy, showed the presence of yeast *Dekkera anomala* found in kefir (Garofalo *et al.*, 2015).

Butter is made from milk, cream or both. It is one of the popular varieties of dairy product because of its high nutritive value (El-Diasty and Salem, 2009).

Yogurts are milky products that are produced using probiotics strains *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* (Mañworé *et al.*, 2019). In fact, yogurts are less contaminated by fungi than cheeses (Boor *et al.*, 2017).

Cheeses are known as a first class food products because of high content of proteins (casein), fat, calcium, magnesium, potassium, phosphate, minerals and vitamins (mostly vitamin D) (El-Diasty and Salem, 2009; El-Badry and Raslan, 2016; Hameed, 2016). Cheeses have a very complex microflora that is divided into two groups: starters and secondary flora. Starters are

Table 3 The occurrence of fungi in different countries

Country	Farms type and number	Results	Conclusion	Reference
Spain (Europe)	50 samples from commercial lot	Fungi: <i>Aspergillus</i> , <i>Penicillium</i> , <i>Myrothecium</i> , <i>Paelomyces</i> , Yeast: <i>Torulopsis candida</i>	Contamination caused by poor hygiene in manufacturing practices during packaging	Medina and Jordano (1993)
Republic of Benin (Africa)	42 samples from 12 farms and 6 markets	Molds and yeast were detected but no data about isolates are available	Contamination caused by poor hygiene during milking	Farougou <i>et al.</i> (2012)
Hungary (Europe)	297 samples from 4 geographical locations: lowlands, hill-mountainous, alluvial plains by the river and sub-mountainous and part by the river	The most frequent were fungi: <i>Fusarium</i> (hilly mountains in spring), <i>Penicillium</i> (hilly mountains in summer as well as sub-mountainous and part by the river in winter) and <i>Cladosporium</i> (sub-mountainous and part by the river in autumn)	The percentage of molds depending on geographical location and season of the year	Pešić-Mikulec <i>et al.</i> (2005)
Latvia (Europe)	547 samples from 14 organic farms from different regions of Latvia	Main detected fungi were of genera <i>Mucor</i> , <i>Absidia</i> , <i>Aspergillus</i> , <i>Penicillium</i> , <i>Geotrichum</i> , <i>Rhizopus</i> , <i>Apophysomyces</i> , <i>Trichoderma</i> , <i>Scopulariopsis</i> , <i>Cladosporium</i> , <i>Chateomium</i> , <i>Cunninghamella</i> , <i>Fusarium</i> and <i>Sepedonium</i>	Occurrence of fungi depends on the location and season of the year	Gulbe and Valdovska (2014)
Quebec (Canada)	19 dairy farms from 6 region of Quebec	The most abundant species were: <i>Debaryomyces hansenii</i> . Nevertheless, there were also isolates of <i>Candida</i> (<i>C. glabrosa</i> , <i>C. parapsilosis</i> , <i>C. zeylanoides</i> , <i>C. tropicalis</i> , <i>C. rugosa</i> , <i>C. apicola</i> , <i>C. catenulata</i> , <i>C. glabrata</i> , <i>C. intermedia</i> , <i>C. pararugosa</i> , <i>C. silvae</i>), <i>Cryptococcus</i> , <i>Galactomyces</i> , <i>Issatchenkia</i> , <i>Nakazawaea</i> , <i>Pichia</i> , <i>Rhodotorula</i> , <i>Trichosporon</i> , <i>Trichothecium</i> , <i>Yarrowia</i> , <i>Lichtheimia corymbifera</i> , <i>Acremonium</i> , <i>Fusarium</i> , <i>Eurotium</i> , <i>Cladosporium</i> , <i>Penicillium</i> , <i>Gibberella</i> , <i>Phaeosphaeria</i> , <i>Phoma</i> and few other (but with no significant significance).	Microbiota of milk can vary from other farms. In most cases	Lavoie <i>et al.</i> (2012)
Poland (Europe)	66- quarter-milk from 44 cows with clinical or subclinical mastitis on small farms in Łomża or near Warsaw	<i>Candida parapsilosis</i> , <i>Candida krusei</i> , <i>Candida lusitanae</i> , <i>Candida famata</i> , <i>Candida guilliermondii</i> , <i>Candida tropicalis</i> , <i>Candida albicans</i> , <i>Cryptococcus</i> , <i>Trichosporon</i> , <i>Saccharomyces</i> , <i>Rhodotorula</i> , <i>Geotrichum</i>	The number of mammary gland infections caused by <i>Candida</i> species has been increasing in the recent years are	Dworecka-Kaszak <i>et al.</i> (2012)
Algeria (Africa)	304 cows of different breeds	<i>Candida</i> , <i>Trichosporon</i> , <i>Rhodotorula</i> <i>Saccharomyces</i>	<i>Candida</i> spp can cause the mammary gland infections	Ksouri <i>et al.</i> (2015)
Poland (Europe)	Cows with clinical symptoms of mastitis on small farms in Łomża or near Warsaw	<i>Candida</i> , <i>Trichosporon</i> , <i>Geotrichum</i> ,	<i>Candida</i> is an etiological factor for mastitis	Krutkiewicz <i>et al.</i> (2011)
Spain (Europe)	20 farms from Castilla La Mancha region – ewe's milk	The most frequently species was <i>Geotrichum candidum</i> . Also were detected <i>Fusarium</i> , <i>Cladosporium</i> , <i>Aspergillus</i> , <i>Penicillium</i> , <i>Trichosporon asahii</i> , <i>Lichtheimia ramosa</i>	<i>Geotrichum candidum</i> is the natural member of the microbiota in raw milk, <i>Trichosporon asahii</i> , <i>Lichtheimia ramosa</i> are an etiologic agents of mastitis	Marín <i>et al.</i> (2015)
Sudan (Africa)	160 camel's milk samples originating from different farms in Bahri (Khartoun North)	Fungi were not isolated. However, the samples were really contaminated by bacteria.	Camel milk should be pasteurized and heated before drinking. The udder and the worker's hands should be washed before milking	Elhaj <i>et al.</i> (2014)

Table 4 The occurrence of fungi in different countries

Country	Dairy products type and number	Results	Conclusion	Reference
Slovenia (Europe)	14 curd samples, 13 soft cheese samples, 13 semi-hard cheese samples	<i>Geotrichum</i> , <i>Aspergillus</i> , <i>Mucor</i> , <i>Fusarium</i> , <i>Moniliella</i> , <i>Penicillium</i>	The curd samples were more contaminated than cheese samples. It was probably caused by improper processing hygiene conditions	Torkar and Vengušt (2008)
Italy (Europe)	54 crust samples	<i>Penicillium</i> , <i>Aspergillus</i>	<i>Aspergillus</i> spp and <i>Penicillium</i> spp are important members of the grana cheese	Decontardi <i>et al.</i> (2018)
Serbia (Europe)	23 total samples of raw milk, infant food, pasteurized milk, whey, yogurt	Mainly <i>Geotrichum candidum</i> in samples of raw milk, infant food, pasteurized milk and in yogurt. <i>Aspergillus</i> was dominant in whey samples	It is important to take prophylactic measures to prevent factors of mycotoxin produce	Jankovic <i>et al.</i> (2009)
Egypt (Africa)	5 samples of raw milk, 5 samples of plain yogurt, 5 samples of kareish cheese, 5 samples of butter	In all products (mostly): <i>Aspergillus brasiliensis</i> , <i>Aspergillus flavus</i> , <i>Cladosporium sphaerospermum</i> , <i>Mucor circinelloides</i> , <i>Penicillium chrysogenum</i> , <i>Candida metapsilosis</i> , <i>Candida orthopsilosis</i> , <i>Candida parapsilosis</i> , <i>Candida zeylanoides</i> , <i>Cyberlindnera jadinii</i> , <i>Debaryomyces hansenii</i> , <i>Galactomyces candidus</i> , <i>Kazachstania unispora</i> , <i>Kluyveromyces marxianus</i> , <i>Myerozyma guilliermondii</i> , <i>Pichia exigua</i> , <i>Rhodotorula mucilaginosa</i> , <i>Trichosporon asahii</i>	The contamination of this products can come from environment	Moubasher <i>et al.</i> (2018)
Egypt (Africa)	Kareish cheese, Damietta cheese, processed cheese, 50 samples each	Kareish cheese: <i>Aspergillus fumigatus</i> , <i>Aspergillus niger</i> , <i>Penicillium corylophilum</i> , <i>Cladosporium cladosporidis</i> . Damietta cheese: <i>Rhizopus</i> spp., <i>Syncephalastrum</i> spp., <i>Paecilomyces</i> spp., <i>Aspergillus versicolour</i> , <i>Aspergillus fumigatus</i> , <i>Aspergillus niger</i> , <i>Aspergillus terreus</i> , <i>Penicillium corylophilum</i> , <i>Cladosporium cladosporidis</i> , <i>Nigrospora</i> spp. Processed cheese: <i>Paecilomyces</i> spp., <i>Aspergillus fumigatus</i> , <i>Aspergillus niger</i> , <i>Aspergillus terreus</i> , <i>Penicillium corylophilum</i> , <i>Cladosporium cladosporidis</i> , <i>Ulocladium</i> spp All kind of cheese: <i>Candida albicans</i> , <i>Candida krusei</i> , <i>Debaryomyces hansenii</i>	Cheese which is treated by Natamycin can have extended shelf-life	Hameed (2016)
USA (North America)	hard, very hard, semi-hard and semi-soft cheese, soft fresh cheese (cottage cheese, mozzarella, feta, ricotta, cream cheese), washed rind cheese and Spanish cheese	<i>Debaryomyces hansenii</i> , <i>Galactomyces candidus</i> , <i>Candida parapsilosis</i> , <i>Candida sake</i> , <i>Candida batistae</i> , <i>Kluyveromyces lactis</i> , <i>Pichia kudriavzevii</i> , <i>Yarrowia lipolytica</i>	Differences of yeasts and fungi isolated can be observed between cheeses type. It is difficult to learn if species are present due to the starter culture or the contamination from other sources like environment, workers etc.	Banjara <i>et al.</i> (2015)
Great Britain (Europe)	British blue-veined cheese Stilton (one – 7.56 kg)	<i>Penicillium roqueforti</i> , <i>Yarrowia lipolytica</i> , <i>Debaryomyces hansenii</i> , <i>Kluyveromyces lactis</i> , <i>Trichosporon ovoides</i>	The results showed that microflora in Stilton cheese is different in the sections of it	Gkatzionis <i>et al.</i> (2014)

China (Asia)	Hurood and Jueke cheese, also raw milk (two batches each)	<i>Kluyveromyces</i> , <i>Pichia</i> , <i>Geotrichum</i> , <i>Galactomyces</i> , <i>Torulaspora</i> , <i>Candida</i> , <i>Naumovozyma</i> , <i>Hanseniaspora</i>	From the same region but different time, microflora is different	Gao et al. (2017)
Serbia (Europe)	3 traditional Serbian cheese	<i>Debaryomyces hansenii</i> , <i>Kluyveromyces lactis</i> , <i>Candida zeylanoides</i> , <i>Trichosporon ovoides</i> , <i>Candida parargosa</i> , <i>Torulaspora delbrueckii</i> , <i>Galactomyces geotrichum</i> , <i>Yarrowia lipolytica</i>	Different detection methods can detecting different species	Šuranská et al. (2016)
France (Europe)	hard cheese (48 samples), butter (1 sample), cream (2 samples), cream cheese (8 samples), pasteurized milk (2 samples), yogurt (4 samples), fresh cheese (6 samples), yogurt drink (3 samples)	Fungi species: Hard cheese: <i>Cladosporium sphaerospermum</i> , <i>Mucor (circinelloides, racemosus, spinosus)</i> , <i>Penicillium (antarcticum, brevicompactum, chrysogenum, commune, discolor, nalgiovense, nordicum, palitans, roqueforti, solitum)</i> , <i>Thamnidium elegans</i> , <i>Debaryomyces hansenii</i> , <i>Sporodibolus salmonicolor</i> , <i>Yarrowia lipolytica</i> Butter: <i>Cladosporium phyllophilum</i> Cream: <i>Penicillium (adametzioides, charlsii)</i> , <i>Meyerozyma guilliermondii</i> Pasteurized milk: <i>Cladosporium halotolerans</i> , <i>Penicillium charlesii</i> Yogurt: <i>Penicillium (bialowiezense, solitum)</i> , <i>Candida parapsilosis</i> , <i>Meyerozyma guilliermondii</i> Fresh cheese: <i>Candida parapsilosis</i> , <i>Kluyveromyces marxianus</i> , <i>Pichia fermentans</i> , <i>Rhodotorula mucilaginosa</i> , <i>Trichosporon asahii</i> , <i>Yarrowia lipolytica</i> . Cream cheese: <i>Didymella pinodella</i> , <i>Exophiala</i> sp., <i>Penicillium (fellutanum, palitans)</i> , <i>Candida inconspicua</i> , <i>Cryptococcus pseudolongus</i> , <i>Galactomyces geotrichum</i> , <i>Kluyveromyces lactis</i> Yogurt drink: <i>Didymella pinodella</i> , <i>Penicillium (commune, solitum)</i> , <i>Candida intermedia</i> , <i>Galactomyces geotrichum</i>	Despite the used of preservatives the contamination of dairy products is still present	Garnier et al. (2017b)

lactic acid bacteria, the function of which is to produce lactic acid during fermentation of lactose. The secondary flora includes bacteria and fungi that might contribute to the development of organoleptic properties (Marín *et al.*, 2015). Yeasts can support the function of starter culture of lactic acid bacteria through the assimilation of lactate and formation of alkaline metabolites. The main supporting function of yeasts are the formation of aroma compounds and flavoring activity. These yeasts can be e.g.: *Yarrowia lipolytica*, *Debaryomyces hansenii*, *Kluyveromyces lactis* (Šuranská *et al.*, 2016).

The production area has a significant impact on the cheese making process. For example, specific environmental conditions are associated with traditional cheese production, which has characteristic aroma, texture and taste (Panelli *et al.*, 2013).

Although fungi are important in pasteurized milk, especially when they are used for the production of cheese and other dairy products. A feature characteristic of some types of ripening cheese with fungi is extensive proteolysis and lipolysis (Torkar and Vengušt, 2008). Contamination of dairy products by fungi can come from the environment, air, equipment, handlers, packaging materials, farm workers, cheesemakers, brine, walls or shelves of ripening rooms (Lavoie *et al.*, 2012; Pal, 2014; Zastempowska *et al.*, 2016; Buehler *et al.*, 2017; Moubasher *et al.*, 2018). The spoilage of dairy products can even originate from water, milk or inadequate infrastructures for milk transportation to the processing facilities (Amaechi and Adiele, 2015; El-Badry and Raslan, 2016).

Fungi are sometimes visible on the surface of butter, cheese and old cream. They often grow in large quantities in the form of a fluffy growth. Dark patches inside the butter suggest the presence of *Cladosporium*, and the most common fungi on cheese is *Penicillium* (Elbagory *et al.*, 2014; Pal, 2014).

Dairy products, like yogurts and cheeses, are more susceptible to spoilage by fungi and yeasts, because there are a lot of strains that grow at low temperatures and low pH (El-Diasty and Salem, 2009; Boor *et al.*, 2017; Buehler *et al.*, 2017; Moubasher *et al.*, 2018). In addition, there is a lot of kind of cheeses that have reduced water activity and also high concentration of salt, thus they have good conditions for some species of fungi to grow (Buehler *et al.*, 2017). Moreover, yeast can assimilate organic acids (such as succinic, lactic or citric) and they are also resistant to cleaning and disinfecting agents (Elbagory *et al.*, 2014). In the cheese production, fungi and yeasts can be also undesirable, because they change the flavor, make an off-odor, make an anomalous textures, discolorations, deformation of the packets containing the cheese and accumulate mycotoxins (Bullerman, 1981; Sengun *et al.*, 2008; Elbagory *et al.*, 2014; Marín *et al.*, 2015; Hameed, 2016; Garnier *et al.*, 2017b; Moubasher *et al.*, 2018). In cheeses, sometimes a source of fungi can be the cheese rind, because during cheese slicing, fungi can be transferred to cheese surface (Garnier *et al.*, 2017a). Yeasts can produce alcohol and CO₂, resulting in yeasty taste of these dairy products (Moubasher *et al.*, 2018). Also yeast can come from brine, surface, equipment, or ingredient contaminations (Garnier *et al.*, 2017b). However, there are a lot of cheeses, such as in blue-veined varieties (e.g., Roquefort or Cabrales) and surface mold-ripened cheeses (e.g., Brie or Camembert), in which the actions of fungi are necessary to develop an appearance, texture and flavor profile (Marín *et al.*, 2015). These fungi are: *Penicillium camemberti* and *Penicillium roqueforti* (Hymery *et al.*, 2014). Also fungi and yeasts are added to cheeses to provide a characteristic consistency, aroma and prolong the shelf life (Lavoie *et al.*, 2012; Banjara *et al.*, 2015; Moubasher *et al.*, 2018). This fungal species added to dairy products are: *Debaryomyces hansenii*, *Candida catenulata*, *Galactomyces geotrichum*, *Kluyveromyces marxianus*, *Mucor lanceolatus*, or *Saccharomyces cerevisiae* (Garnier *et al.*, 2017a). Also these fungi are: *Aspergillus*, *Cladosporium*, *Geotrichum* and *Trichoderma* (Hymery *et al.*, 2014). These cheeses are mostly blue-veined, such as the French Bleu and Roquefort, the Italian Gorgonzola, the English Stilton, the Danish Danablu or the Spanish Cabrales, Picón Bejes-Tresviso, and Valdeón (García-Estrada and Martín, 2016; Ropars *et al.*, 2017). In addition, *Geotrichum candidum* is added to Camembert and Brie (Dupont *et al.*, 2017). In fact, the presence of *Penicillium roqueforti* contributes to the aerobic conditions that can result in a blue-vein appearance (Gkatzionis *et al.*, 2014; Ropars *et al.*, 2017; Yunita and Dodd, 2018).

In 1997, the study was conducted in Brazil. Samples of yogurt were collected from local manufactures and supermarkets from South of Minas Gerais. In tested samples, following species were isolated: *Debaryomyces hansenii*, *Saccharomyces cerevisiae*, *Hansenula* spp., *Mrakia frigida*, *Candida parapsilosis*, *Debaryomyces castellii*, *Candida maltose*, *Schizosaccharomyces pombe*, *Candida mogii*, *Kluyveromyces marxianus*. The *Mrakia frigida* was the first time reported in yogurts. The authors concluded that warmer weather and inadequate refrigeration are the main reasons for higher levels of contamination (Moreira *et al.*, 2001). (Table 4).

Conclusions

Contaminated milk and dairy products are available almost all over the world. This paper shows that various kinds of fungi can be present in different types of milk and dairy products. Since now, up to 100 of fungi species have been identified as being responsible for dairy products spoilage. For example, *Penicillium* spp. are mainly isolated from hard and semi-hard cheeses, but they are also found in all other product types, including fresh, blue-veined, mould-ripened, soft- and semi-soft cheeses, butter, yogurt, milk as well as in buffalo, goat, or ewe's milk cheeses (Garnier *et al.*, 2017a). Also in milk samples, there were detected several fungi like *Aspergillus*, *Penicillium*, *Myrothecium*, *Paelomyces*, *Mycogene*, *Mucor*, *Absidia*, *Geotrichum*, *Rhizopus*, *Apophysomyces*, *Trichoderma*, *Scopulariopsis*, *Cladosporium*, *Chateomium*, *Cunninghamella*, *Fusarium*, *Sepedonium*, *Lichtheimia*, *Malassezia* and yeast like *Candida*, *Cryptococcus*, *Galactomyces*, *Issatchenkia*, *Nakazawaea*, *Pichia*, *Rhodotorula*, *Trichosporon*, *Trichothecium*, *Yarrowia*, *Saccharomyces*. In addition, the most abundant species in dairy products are fungi such as: *Geotrichum* (cheeses, yogurts), *Penicillium* (cheeses, yogurts, butter, cream), *Aspergillus* (cheeses, whey, yogurt, butter), *Mucor*, *Cladosporium* (cheeses, yogurts, butter), *Fusarium*, *Moniliella*, *Rhizopus*, *Syncephalastrum*, *Paecilomyces*, *Nigrospora*, *Thamnidium* (cheeses) and yeasts: *Dekkera* (kefir), *Kluyveromyces*, *Galactomyces*, *Candida* (cheeses, yogurts, butter, cream), *Debaryomyces*, *Cyberlindnera*, *Kazachstania*, *Myerozyma*, *Pichia*, *Rhodotorula*, *Trichosporon* (cheeses, yogurts, butter), *Saccharomyces*, *Hansenula*, *Mrakia*, *Schizosaccharomyces*, *Meyerozyma* (yogurts), *Yarrowia*, *Torulaspora*, *Naumovozyma*, *Hanseniaspora* (cheeses), *Cryptococcus* (cream).

Determining the sources of fungi in products consumed daily is extremely important, because it helps to prevent future contaminations. It will also estimate any associated potential health risk (ElBagory *et al.*, 2014), especially because there is a lot of factors which can cause the growth of fungi and yeasts.

Preventive measures that should reduce the occurrence of fungi contamination on these products are very important for an economic reason – contaminated products are not suitable for sale (El-Badry and Raslan, 2016; Vimont *et al.*, 2019). Fungi can change the characteristics of milk, cheese, yogurt, etc, thus products can become not tasty.

Profile of Fungi in Dietary Supplement, Based on Plant Raw Material

Iwona Altn and Magdalena Twarużek, Kazimierz Wielki University, Bydgoszcz, Poland

Introduction

Herbal plants are used as everyday products and as raw materials in the pharmaceutical industry for the production of, among others, dietary supplements for the use and treatment of diseases; however, they may not meet the quality, safety, and efficacy requirements of the treatment (World Health Organization, 2001,2005). According to the WHO, herbal medicines are defined as herbal products in the medicines category in a national drug regulatory framework, therefore they may include “herbs”, “herbal materials”, “herbal preparations”, and “finished herbal products”/“herbal medicinal products” (World Health Organization, 2007). The World Health Organization (2014–2023) confirms the use of phytotherapy is popular and is the main source of health care primarily in countries with less availability of conventional medicine, but also in developed countries or as complementary therapy used by about 70% of Australians and one-third of Americans (Complementary Medicines Australia, 2017). Global market for medicinal plants is constantly growing, for 2016 it was valued at 71.19 billion USD by Hexa Research (2017) and Rocha-Miranda and Venâncio (2019). The medicinal plant consists of many active chemicals, such as mucilage, polyphenols, polysaccharides, etc., which may modify the effects of the active principles. Thus, it is believed that some natural remedies may have toxic effects on the body or act as an agonist or antagonist of the active substance (Dar et al., 2013). Therefore, toxicity tests for pre-assessment of the efficacy of plant extracts are so important (Hewawasam et al., 2016).

Herbal plants are exposed to different types of pollution, from chemical to microbiological, which have negative impact on human body. Examples of potential sources of contaminants as well as manufacturing stages, during which they may be detectable, are shown in Table 1.

Dietary supplements are foodstuffs and they must comply with the definition of food in Regulation (EC) No 178/2002 of the European Parliament and of the council of 28 January 2002 (European Commission, 2002), according to which: “food (foodstuff) means any substance or product, processed, partly processed or unprocessed, intended for human consumption or the consumption of which by people can be expected.” Current legal regulations do not have guidelines for ingredients of dietary supplements other than vitamins and minerals, which means that the market for these products is characterized by considerable diversity. According to a report from the European Commission (SEC, 2008), the number of substances used in the production of dietary supplements is about 400, of which 50% of the dietary supplements market in the European Union are vitamins and minerals (Table 2). Dietary supplements contain mostly plant raw materials traditionally used in Europe, including pharmacopoeia raw materials; however, they should be in supplements at doses much lower than the therapeutic ones.

Under current law, trade of a dietary supplement does not require authorization, as is the case with medicinal products. Therefore, most of these products are not tested and their use is monitored poorly or not at all. The cause of negative impact of dietary supplements on a body may be contamination by various mold fungi during collection of plant ingredients, use, packaging, and distribution. Almost 80% of deaths in Poland result from the so-called civilization diseases, i.e., in the study of cardiovascular diseases – approx. 48%, malignant cancers – approx. 24%, and injuries and poisonings – approx. 7% (Altn et al., 2018). Organizations dealing with the issue of food, i.e., the Food and Agriculture Organization (FAO), The World Health Organization (WHO), and the EU Food Safety Commission (EFSA) see the risk of using fungi as quite realistic, which is why committees have been flooding in recent years to assess the toxicity of them in foodstuffs. World market of medicinal herbs in 1985 was estimated to ~ \$17 billion, while current market analysis shows that by 2023 it will increase to ~ \$111 billion (average annual growth rate of 7%–8%). Factors that increase the demand include the cost of insurance-based medical care in some areas (America), growing desire of people in industrialized countries to take over their own health, and increasingly older population in these countries (Market Research Futures, 2018).

Occurrence of Fungi in Plants and Dietary Supplements – A Global Problem

Molds form a group of about 100,000 species and are widespread in nature. They are one of the most common environmental pollutants, due to their high ability to multiply under favorable conditions, on virtually any substrate (Ahmad et al., 2014). It is estimated that about 25% of the biomass share is mold (Hussein and Brasel, 2001). From an ecological point of view, they play an important role in the natural circulation of matter, because they contribute to the degradation of biomass making it again useful as a nutrient. At the same time, however, as pathogens they are important in crops (especially cereals), causing a decrease in yield and a decrease in their quality.

Mold infection of raw materials and products (especially plant ones) and, as a result, the mycotoxin load is not uniform every year, therefore the problem in question is eagerly silenced, hence it is still underestimated. The most important types of mold fungi include: *Aspergillus* spp., *Penicillium* spp., *Fusarium* spp., *Alternaria* spp., *Claviceps* spp. They can be formed either by primary phytopathogenic species of fungi (e.g., *Fusarium graminearum*), already on plants growing in the field, or during storage of foodstuffs, raw materials and feed, under conditions favorable for their development (e.g., *Penicillium* spp).

Table 1 Classification of major contaminants and residues in herbal medicines

General classification	Group	Subgroup	Specific examples	Possible sources
Chemical contaminants	Toxic and hazardous materials	Toxic metals and non-metals	Lead, cadmium, mercury, chromium (arsenic, nitrite)	Polluted soil and water, during cultivation/growth, manufacturing process
		Persistent organic pollutants	Dioxin aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, mirex	Polluted air, soil and water, during cultivation/growth
		Radionuclide	Cs-134, Cs-137	Air, soil, water during cultivation/growth
		Biological toxins	Mycotoxins Bacterial endotoxins	Post-harvest processing, transportation and storage Post-harvest processing, transportation, and storage
Biological contaminants	Microorganisms	Bacteria	<i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i> , <i>Salmonella</i> species, <i>Shigella</i> species, <i>Escherichia coli</i>	Soil, post-harvest processing, transportation and storage
		Fungi	Yeast, molds	Post-harvest processing, transportation, and storage
	Animals	Parasites	Protozoa–amoebae, Helminths–nematoda	Soil, excreta; organic farming/cultivation, manufacturing process
		Insects	Cockroach and its parts	Post-harvest processing, transportation, and storage
		Others	Mouse excreta, earthworms, acarus	Post-harvest processing, transportation, and storage
Solvents	Organic solvents	Acetone, methanol, ethanol, butanol	Soil and water, Turing cultivation/growth, Manufacturing process	
<i>Residues</i>				
General classification	Group	Subgroup	Specific examples	Possible sources
Agrochemical Residues	Pesticides	Insecticides	Carbamate, chlorinated hydrocarbons, organophosphorus	Air, soil, water, during cultivation/growth, postharvest processing
		Herbicides	2,4-D, 2,4,5-T	Air, soil, water, during cultivation/growth, postharvest processing
		Fungicides	Dithiocarbamate	Air, soil, water, during cultivation/growth
	Fumigants	Chemical agents	Ethylene oxide, phosphine, methyl bromide, sulfur dioxide	Post-harvest processing
	Disease control agents	Antiviral agents	Thiamethoxam	During cultivation
Residual solvents	Organic solvents	Acetone, methanol, ethanol, butanol	Manufacturing process	

Note: Stages of production, at which contaminants are detectable – (1) medicinal plants; (2) herbal materials; (3) herbal preparations; (4) finished herbal products.

World Health Organization, 2007. WHO guidelines for assessing quality of herbal medicines with reference to contaminants and residues. Geneva: World Health Organization.

Table 2 The highest tolerable intake level of some selected nutrients

Nutrient	Acc. to SCF/EFSA ^a	According to IOM ^b	According to EVM ^b
Biotin (μg)	–	–	900 (GL in food)
Folic acid (μg)	1000(Ref. only to folic acid supplements)	1000	1000 (GL in food)
Nicotinic acid (mg)	10	35 (niacin)	17 (GL in supplements only)
Nicotinamide (mg)	900	35 (niacin)	560 (GL)
Vitamin B ₆ (mg)	25	100	10 (SUL in food)
Vitamin C (mg)	–	2000	–
Vitamin A (retinol) (mg)	3000 (does not refer to post-menopausal women)	3000	1500 (GL)
B – carotene (mg)	–	25 (ref. to smokers)	7 (SUL in supplements only)
Vitamin D (μg)	50	50	25 (GL in food)
Vitamin E (mg)	300	1000	800 (SUL in foods)
Calcium (mg)	2500	2500	1500 (GL in food)
Phosphorus (mg)	–	4000	250 (GL in food)
Magnesium (mg)	250 (Ref. to supplements)	350	400 (GL in food)
Iron (mg)	–	45	17 (GL in food)
Zinc (mg)	25	40	25 (SUL in foods)
Copper (mg)	5 (does not refer to women during pregnancy and breastfeeding)	10	10 (SUL)
Fluoride (mg)	7 (Ref. to children above 8 years and adults)	10	–
Iodine (μg)	600	1100	500(GL in addition to food)
Selenium (μg)	300	400	450 (SUL)
Molybdenum (μg)	600	2000	–

^aDetermined as UL – the highest tolerable level.

^bIt is a GL value – tolerable level or as SUL value – the max safe level.

Note: Krasnowska, G., Sikora, T., 2011. Suplementy diety a bezpieczeństwo konsumenta. Żywność. Nauka. Technologia. Jakość 4 (77), 5–23.

Diseases called mycoses (aspergillosis, mucormycosis, penicilliosis) are included in the direct disease effects caused by fungi. They cause generalized and organ (invasive) mycoses as well as allergies. Fungal allergens (spores and fragments of fungi) are transferred with air bioaerosol. After entering the respiratory system, as well as remaining outside the body, especially in people and animals susceptible to allergies, they cause responses such as bronchial asthma, conjunctivitis, allergic rhinitis, up to alveolitis (Grajewski, 2006).

Some mold species are able to produce mycotoxins in the material to such an extent that negative effects may occur not only on the yield and quality of the raw material, but also on human and animal health. The insight that this group of natural, structurally very different toxic substances is formed by molds, is slowly occurring not only in pistachios, peanuts or dried figs, as well as in local crops or the human habitat (damp housing) and can be a cause of poisoning, slowly breaks through. Both own research and conducted by global scientific centers confirm that dangerously high levels of molds contamination are present in herbs, medicinal plants, as well as dietary supplements, which can pose a threat to human health (Grajewski, 2006).

Since the middle of the 20th century, researchers have identified the presence of fungi in herbs and dietary supplements. One of the first reports on the fungal spoilage of plant-based drugs was showed by Matsushima *et al.* (1958) and Kallings *et al.* (1966). Hitokoto *et al.* (1978) report of molds contamination of herbal plants in 1978. In their study, the results showed that *Aspergillus* and *Penicillium* species were predominant, but *Rhizopus*, *Mucor*, *Cladosporium*, and *Aureobasidium* spp. were also found in a few samples. Molds contamination of herbal drugs from Japan and India was also reported by Yamazaki *et al.* (1980). Results of their work showed that 17 out of 50 samples were contaminated. *Aspergillus* and *Fusarium* species (54% and 24%, respectively) were the most frequent from Indian drugs. Halt (1998) analyzed the level of molds in medicinal plants and herbal tea. The dominant fungi detected were *Aspergillus*, *Penicillium*, *Mucor*, *Rhizopus*, *Absidia*, *Alternaria*, *Cladosporium*, and *Trichoderma* species. In 81 different samples, divided into 3 groups: final products (EP), raw material (RM), and during harvest (SH), degree of fungal contamination as well as the occurrence of natural *Aspergillus flavus* were examined. In all samples, the number of fungi did not exceed the international mandatory limits. The dominant species were *Aspergillus* (100%), *Penicillium* (<50%), and to a lesser extent *Fusarium* (5.6%). *A. flavus* was present in all three groups of samples (Rizzo *et al.*, 1998). Research conducted by Efuntoye (1996, 1999) in terms of the occurrence of fungi in sun dried herbal drugs from Nigeria showed that twenty-eight fungal species were isolated, with *A. niger*, *Aspergillus flavus*, *Fusarium verticillioides*, *Trichoderma viride*, *Penicillium expansum* and *Mucor fragilis* being the dominant ones.

In research conducted by Bugno *et al.* (2006), 10 types of fungi were identified in medicinal plants from Brazil, where 55% of samples exceeded the maximum limit of the fungi number set by the US Pharmacopoeia (10^2 cfu g⁻¹). The genus *Aspergillus* was the most common (90%) followed by *Penicillium* (40%). Also Singh *et al.* (2008) studied fungal contamination in six medicinal plant samples, viz. *Adhatoda vasica* Nees, *Asparagus racemosus* Linn., *Evolvulus alsinoides* Linn., *Glycyrrhiza glabra* Linn., *Plumbago zeylanica* Linn., and *Terminalia chebula* Retz. A total of 858 fungal isolates were detected from the analyzed samples, of which the *Aspergillus* genus was the most dominant causing infection of most raw materials. Also Ahmad *et al.* (2014) reported that in 70% of medicinal plant samples, the level of molds exceeded the permissible limits determined by the United States Pharmacopoeial Convention Inc. (2005). These results are in agreement with findings of Abou-Arab *et al.* (1999) and Abou Donia (2008). Results

of Jahani *et al.* (2013) work showed the fungal contamination of barberry, with the high frequency of *Aspergillus*, *Penicillium* genus. Findings of Filipiak-Szok *et al.* (2016) showed that in the dietary supplements, the sum of molds and yeasts was lower than 69 cfu g^{-1} . Ting *et al.* (2013) showed molds contamination in traditional herbal medicines. *Bacillus* spp. was the most prevalent molds, and was detected from 7 of 8 samples. The least commonly recovered was the *Clostridium* spp. and *Staphylococcus* spp., detected only in 2 samples. In study by Sharma *et al.* (2014), a total of 16 fungal species belonging to 7 different genera, were isolated from the collected samples. *Aspergillus* was recorded as the most dominant genus with 9 species. *A. niger* was the most predominant species with occurrence frequency of 63.33%.

Tournas *et al.* (2006) analyzed 46 ginseng supplement samples including Siberian ginseng root, Chinese ginseng herb and root, and American ginseng root. Seventy eight percent of the ginseng herb, 100% of the Siberian, 56% of the Chinese, and 48% of the American ginseng root samples showed fungal contamination. The highest contamination ($4.3 \times 10^5 \text{ cfu g}^{-1}$) was observed in the locally grown American ginseng root and the lowest ($< 100 \text{ cfu g}^{-1}$) in ginseng extract. Fungi found in ginseng herb were *A. alternata*, *Aspergillus niger*, *Aspergillus*, *Cladosporium* and *Penicillium* spp., *Eurotium chevalieri*, *Rhizopus* spp., and yeasts. In 2009, research conducted by Tournas showed the presence of mold and yeast in herbal products and dietary supplements. The most common molds belonged to the genera *Aspergillus* spp., *Penicillium* spp., and *Eurotium* spp. The highest amount of mold and yeast was found in alfalfa supplements ($5.6 \times 10^6 \text{ cfu g}^{-1}$), while the lowest in ginger supplements ($1.0 \times 10^2 \text{ g}^{-1}$). Subsequent research conducted by Filipiak-Szok *et al.* (2016) concerned the contamination of dietary supplements and plant extracts, such as ginseng. Test results confirmed a high degree of contamination by fungi (*Cladosporium* spp., *Eurotium* spp., *Aspergillus* spp., *Rhizopus* spp., and *Penicillium* spp.). Rajeshwari and Raveesha (2016) studied herbal preparations for the presence of microorganisms, including molds. Eighteen herbal substances were tested, including Ashwagandha. Only in 6 of the tested materials, there was the presence of fungi. The most commonly isolated molds belonged to the genus *Aspergillus* spp. (20%) and *Penicillium* spp. (17%). *A. niger* was the most common mold species followed by *A. flavus*. In 2018, Su *et al.* (2018) analyzed eight RHs (e.g., Chinese yam, American ginseng, ginseng, astragalus, polygala, bupleurum, and liquorice), i.e., 48 samples in total (6 samples for each herb). Results showed that all 48 samples were contaminated by molds, with level from 1.08 to 4.391 log cfu g⁻¹, but samples did not exceed the maximum limit of 10^5 cfu g^{-1} (equivalent to 5 log cfu g⁻¹) set by the WHO for raw medicinal plants.

Green coffee and its extracts are included in dietary supplements that support the slimming process. Previously, they were not included in products endangering human health and life, because they were not consumed in this form. Research conducted by Twarużek *et al.* (2015) showed significant contamination of green coffee samples. The test material was dominated by molds of the genus *Aspergillus* spp. (63%) and *Penicillium* spp. (25%), while coffee extract was mainly contaminated with *Penicillium* spp. (72%). Research of Haas *et al.* (2013) concerned the content of fungi in Pu-Erh tea – red tea originating in the Yunnan province in southwestern China. It is used as a herbal dietary supplement supporting weight loss, lowers cholesterol and protects against caries. A total of 19 types of fungi were identified in this material, including 31 species, including *Aspergillus acidus* and *Aspergillus fumigatus*, or *Zygomycetes* and *Penicillium*. Also the results of research by Zhao *et al.* (2010) confirm the occurrence of fungi in all samples tested, in the range from 1.6×10^3 to $1.16 \times 10^5 \text{ cfu g}^{-1}$, and 62 isolates were identified as belonging to 41 species from 19 genera, including 13 species of *Aspergillus* and 7 *Penicillium* species and 21 species of other genera. Due to the presence of fungal species such as *Aspergillus fumigatus*, *Penicillium* spp., *Trichoderma* spp., and *Fusarium culmorum*, etc., which can secrete toxic metabolites, further monitoring of the hygienic state of Pu-erh tea products is necessary. Kostecka and Bojanowska (2013) analyzed fresh basil, lemon balm and mint, as well as dried herbs, herbal teas, and dietary supplements. Molds were present in all samples, with the dominant genera: *Aspergillus* and *Fusarium*. Also in the samples there were genera of *Alternaria* and *Penicillium*, followed by *Mucor*, *Rhizopus* and *Uclodium* sp. Similar results were reported by Wójcik-Stopczyńska and Jadczyk (2007) and Wójcik-Stopczyńska *et al.* (2010) in the study of whom, herbs were most frequently colonized by fungal genera of *Alternaria*, *Botrytis*, *Penicillium*, *Fusarium* and *Aspergillus*. One hundred forty-four samples belonging to 48 kinds of dried medicinal plants collected from various markets in the city of Mansoura in the province of Dakahlia were examined for the natural occurrence of mold. Among the analyzed samples, 36 species and 1 variety belonging to 11 genera were isolated. The genus *Aspergillus* (91.7%) was the most common type of fungus followed by *Penicillium* (68.8%). The most common species of fungi were *Aspergillus niger*, *Penicillium chrysogenum*, *Aspergillus flavus* var *columnaris*, and *Aspergillus flavus*, the incidence of which were 75%, 56.3%, 41.7% and 33.3%, respectively (Fatma *et al.*, 2017). One-hundred-fifty dry samples from Egypt, basil, mint, marjoram, chamomile, and fennel were analyzed for contamination by fungi and yeast. The highest number of molds was found in mint, basil, marjoram, fennel and chamomile, in descending order, respectively, while the highest number of yeast was found in chamomile, mint, fennel, basil, and marjoram, respectively. *Aspergillus* spp. *Fusarium* spp., *Penicillium* spp. *Mucor* spp. *A. Humicola* spp. were more frequently detected. Thirty samples of fennel among mold and yeast were also analyzed and it was clear that the number of yeast and mold did not exceed 10^5 cfu g^{-1} . The greatest contamination by mold was present in the case of dry mint, basil, marjoram, fennel and then chamomile. (in descending order). In contrast, the largest count of yeast was present in chamomile, dry mint and fennel. Basil and marjoram showed 10^2 cfu g^{-1} for yeast (Abol-Ela *et al.*, 2011).

In contrast, research conducted by Aiko and Mehta (2016) showed an average content of fungi in stevia samples at the level of 3.5×10^2 , where dominated the genus *Aspergillus* spp., *Fusarium* spp., *Alternaria* spp. Keter *et al.* (2017) analyzed samples collected from Eldoret, Mombasa. In total, 88.2% of powders and 64.3% liquids from Eldoret were contaminated, while oils and control substances (conventional drugs, chlorphenamine, and paracetamol syrups) were not contaminated. Mombasa herbal powders were more contaminated at 84.2% and liquids at 66.7%, tablets 66.7%, while oils, capsules, and controls were not contaminated. Długaszewska *et al.* (2019) analyzed samples (n = 106) were had a mixed fungal contamination pattern with more than one genus present, with the dominant genera isolated from DS and RM, respectively: *Aspergillus* spp. (45.0%; 47.0%), *Alternaria* spp.

(26.3%; 23.0%), *Penicillium* spp. (17.0%; 10.0%), *Fusarium* spp. (1.0%; 7.0%), *Cladosporium* spp. (3.0%; 3.0%). In studies conducted by [Chen et al. \(2020\)](#), the presence of fungi was detected in 48 samples of 13 different medicinal herbs. In all, 83.3% of all samples were contaminated with fungi. Sixty-nine strains were determined, of which four were found to be dominant: *Aspergillus* spp. (26.1%), *Penicillium* spp. (24.6%), *Rhizopus* spp. (14.5%), and *Trichoderma* spp. (11, 6%). [Gajewska and Głowacka \(2017\)](#) conducted a study, the purpose of which was to determine the level of contamination with dried filamentous fungi of dried herbs and spices available in organic stores and hypermarkets in Poland: garlic (*Allium sativum*), dill (*Anethum graveolens*), parsley (*Petroselinum crispum*), basil (*Ocimum basilicum*), oregano (*Origanum vulgare*), tarragon (*Artemisia dracuncululus*), thyme (*Thymus vulgaris*), marjoram (*Origanum majorana*), nutmeg (*Myristica fragans*), curry (*Helichrysum angustifolia*), turmeric (*Curcuma longa*), black pepper (*Piper nigrum*), sweet pepper (*Capsicum annuum*). Mycological analysis showed that filamentous fungi belonging to a total of 5 genera were isolated from dried herbs and spices: *Aspergillus* (*A. niger*, *A. flavus*), *Penicillium*, *Mucor*, *Alternaria*, and *Cladosporium*.

Contamination of plant raw materials and dietary supplements with fungi such as *Aspergillus*, *Penicillium*, *Fusarium*, and *Alternaria* is very dangerous both for humans and animals due to the toxic products of secondary metabolism: mycotoxins, which can cause both acute and chronic toxic effects, and even death ([Food and Agriculture Organization of United Nations, 2001](#)). [Yamazaki et al. \(1980\)](#) showed that 17 out of 50 samples were contaminated by mycotoxins. AFB₁ was the most frequently detected mycotoxin and it was detected above tolerance levels fixed by the World Health Organization. Study of [Su et al. \(2018\)](#) also reported that among 13 isolates of *A. flavus*, five ones from Chinese yam, ginseng, astragalus, and liquorice were found to produce AFB₁ and AFB₂. In the research of [Bugno et al., 2006](#), almost 22% of isolates from medicinal plants were able to produce mycotoxins: 42.9% were aflatoxygenic strains, 22.4% were ochratoxygenic strains, and 34.7% were strains producing citrinine. Also [Singh et al. \(2008\)](#) studied aflatoxin B₁ contamination of six medicinal plant samples, viz. *Adhatoda vasica* Nees, *Asparagus racemosus* Linn., *Evolvulus alsinoides* Linn., *Glycyrrhiza glabra* Linn., *Plumbago zeylanica* Linn., and *Terminalia chebula* Retz. Also [Wu et al. \(2014\)](#) studied previously isolated *Alternaria tenuissima* strain from the of *Tribullus terrestris* L. and found it to be a producer of mycotoxins (altertoxins II and IV). Also samples belonging to 48 kinds of dried medicinal plants collected from different markets in Mansoura city, Dakahlia governorate, were examined for the natural occurrence of aflatoxins. Out of 30 medicinal plant samples screened, 19 samples (63.3%) were found to be contaminated with aflatoxins in the range of 1.5–724.6 ng g⁻¹ ([Fatma et al., 2017](#)). Both own research and conducted by global scientific centers confirm that in herbs, medicinal plants, as well as dietary supplements, dangerously high levels of mycotoxins are also present: aflatoxin (AF), ochratoxin A (OTA), fumonisin (FB), zearalenone (ZEN), which may pose a risk to human health ([Vidal et al., 2013](#); [Trucksess et al., 2009](#); [Tassaneeyakul et al., 2004](#); [Veprikova et al., 2015](#); [Solfrizzo et al., 2015](#); [Ariño et al., 2007](#); [Arroyo-Manzanares et al., 2013](#); [Badreldin et al., 2008](#); [D'Ovidio et al., 2006](#); [Karkanis et al., 2018](#); [Koul and Sumbali, 2008](#); [Lippolis et al., 2017](#); [Zain, 2011](#); [Zhang et al., 2018](#)).

Conclusions

Consumers are increasingly interested not only in the health-promoting properties of medicinal plants and dietary supplements, but also in their safety for health. Results of conducted research confirm that these products are exposed to various types of mycological contaminations, which largely depend on environmental conditions. Contamination can occur at any stage of production, i.e., during cultivation, as well as during harvesting, processing, storage, and transport. Despite many benefits of taking dietary supplements, however, we must remember about their hygienic status, and that, according to the saying of Paracelsus (1493–1541), a Swiss–German doctor: everything is poison, nothing is poison, the action depends only on the dose.

Molds in Food Spoilage

Magdalena Twarużek, Ewelina Soszczyńska, and Justyna Kwiatkowska-Giżyńska, Kazimierz Wielki University, Bydgoszcz, Poland

© 2021 Elsevier Inc. All rights reserved.

Introduction

Food spoilage is a metabolic process that causes foods to become undesirable or unacceptable for human consumption due to changes in sensory characteristics (Sahu and Bala, 2017; Rawat, 2015). The main cause of food spoilage is invasion by microorganisms such as molds, yeast and bacteria. Fungi are ecologically, physiologically and morphologically diverse and constitute one of the largest group of organisms on earth with at least 1.5 million and more probably, close to 3 million species (Hawksworth, 2015; Quéro *et al.*, 2019). Fortunately for the food industry, the number of concern as spoilage agents in food, drink, and water are relatively few; only a few hundred, of which only about 50 are commonly encountered (Hawksworth, 2015). Among fungi, microscopic filamentous fungi (also called molds) have an important impact on human activities, either positive or negative. On one hand, they are important producers of enzymes, organic acids and antibiotics and can be used to manufacture fermented foods (Chalupová *et al.*, 2014; Chen *et al.*, 2014; Rodríguez *et al.*, 2015; Quéro *et al.*, 2019). On the other hand, they are able to spoil a large variety of food and food commodities, from raw materials to finished products. Their growth can lead to several types of product-alteration such as taste and odor problems and decay (Pitt and Hocking, 2009; Quéro *et al.*, 2019). Filamentous fungi cause important food losses and substantial economic damage (Quéro *et al.*, 2019; Thornton and Wills, 2015; Rodríguez *et al.*, 2015).

The exact causes of food losses vary throughout the world and are very much dependent on the specific conditions and local situation in a given country. In broad terms, food losses is influenced by crop production choices and patterns, internal infrastructure and capacity, marketing chains and channels for distribution, as well as consumer purchasing and food use practices. Irrespectively of the level of economic development and maturity of systems in a country, food losses should be kept to a minimum (State of Food and Agriculture, 2019; Rawat, 2015). These losses are very difficult to evaluate, because they fluctuate depending on the location, the season, and the type of product spoiled. For instance, 1%–3% losses were reported in the bakery industry, and 5%–10% losses were reported for postharvest fruits treated with fungicides (Dagnas and Membre, 2013; Rawat, 2015).

The issue of food losses is of high importance in the efforts to combat hunger, raise income and improve food security in the world's poorest countries. Food losses have an impact on food security for poor people, on food quality and safety, on economic development and on the environment. There are also environmental and resource costs associated with food spoilage and loss. If 20% of a crop is lost, then 20% of the fertilizer and irrigation water used to grow that crop was also lost (Rawat, 2015). A new FAO report launched 14 October 2019, Rome – by the UN Food and Agriculture Organization, provides insights into how much food is lost – as well as where and why – at different stages of the food supply chain, calls for informed decisions for an effective reduction and offers new ways to measure progress. FAO report provides with new estimates of food loss from post-harvest up to retail to help identify appropriate measures for an effective reduction. According to the State of Food and Agriculture (2019), globally around 14% of the world's food is lost after harvesting and before reaching the retail level, including through on-farm activities, storage and transportation (State of Food and Agriculture, 2019).

Diversity of Spoilage Fungi

Food spoilage may be defined as a process or change which renders a product undesirable or unacceptable for consumption (Nychas and Panagou, 2011). Spoilage may arise from insect damage, physical damage, indigenous enzyme activity in the animal or plant tissue or by microbial infections. Most natural foods have a limited life. Perishable foods such as fish, meat and bread have a short life span. Other food can be kept for a considerably longer time, but it decomposes eventually. Enzymes can bring about destruction of polymers in some foods, while chemical reactions such as oxidation and rancidity decompose others, but the main single cause of food spoilage is invasion by microorganisms such as molds, yeast and bacteria (Garnier *et al.*, 2017; Rawat (2015)). It has been estimated that 5%–10% of the worldwide food losses is due to the fungal spoilage (Quéro *et al.*, 2019).

Losses are the results of one or more problems occurring in the supply chain, from initial agricultural production down to the consumer level (State of Food and Agriculture, 2019). The moldy foods are the source of various food borne conditions due to gastroenteritis in human. Currently, the emphasis is put on the total quality of food, which means that not only food should be nutritionally balanced but should be microbiologically safe too (Embaby *et al.*, 2015). In this context, correct identification of food fungal spoilage is a key step to better manage the food safety and quality. An erroneous identification could lead to the risk underestimation or unnecessary counter measures (Hawksworth, 2015; Quéro *et al.*, 2019).

Filamentous fungi are also a constraint on food safety issue due to the production of mycotoxins or allergens by these molds. To avoid or reduce the mold spoilage, several hurdles can be used: reducing the water activity of the food, thermal processing, addition of preservatives, reduction of oxygen in the packaging using vacuum, oxygen scavengers or modified atmosphere

packaging (MAP), and refrigerated storage. However, the addition of each of these hurdles can be selected for different groups of spoilage fungi (Rico-Munoz *et al.*, 2019; Rodríguez *et al.*, 2015; Thornton and Wills, 2015). To prevent mold spoilage, it is essential that the associated mycobiota be adequately isolated and accurately identified (Rico-Munoz *et al.*, 2019). The fungi groups associated with fungal spoilage are: xerophilic fungi that can grow at water activity (a_w) below 0.85 and spoil low and intermediate a_w foods; heat resistant fungi that survive pasteurization and baking, spoiling heat-processed products; preservative-resistant fungi that can grow in the presence of preservatives such as sorbates or benzoates and spoil beverages and foods that are preserved; anaerobic fungi that can grow under very low oxygen concentration and spoil vacuum or modified atmosphere packaged foods and psychrophilic and psychrotolerant fungi that can grow under refrigeration and spoil refrigerated foods (Pitt and Hocking, 2009; Rico-Munoz *et al.*, 2019).

Xerophilic Fungi

Xerophilic fungi are defined by the ability to grow under reduced water activity conditions, i.e., to complete their life cycles on substrates that have been dried or concentrated, in the presence of high levels of soluble solids such as salts or sugars (Pitt and Hocking, 2009; Rico-Munoz *et al.*, 2019). First defined by Scott, a_w is related to the water available in the matrix and is generally the dominant factor in the control of food stability and spoilage (Dagnas and Membre, 2013; Pitt and Hocking, 2009). Fungi can be subdivided among two groups (Hocking, 2001; Pitt and Hocking, 2009). The first contains those that are capable of growing at or below 0.85 a_w values, generally known as moderate xerophiles. The second group, known as extreme xerophiles, contains filamentous fungi that either cannot grow at high a_w (i.e., above about 0.96–0.97 a_w) or grow very slowly and consequently compete very poorly in high a_w environments. Many important food spoilage fungi can be described as “moderate xerophiles” such as *Penicillium* species, some *Aspergillus* species (including species with eurotiummorph) and *Paecilomyces variotii*. The most common *Aspergillus* species (with eurotiummorph) are *A. montevicensis* (= *A. amstelodami*), *A. chevalieri* (= *Eurotium chevalieri*), *A. pseudoglaucus* (= *Eurotium repens*), *A. ruber* (= *Eurotium rubrum*) and *A. glaucus* (= *Eurotium herbariorum*) (Chen *et al.*, 2017; Pitt and Hocking, 2009; Samson *et al.*, 2010; Rico-Munoz *et al.*, 2019). They produce mildly heat-resistant ascospores that, under some conditions, can survive heating at 70–75°C for several minutes. These species are widely associated with deterioration of stored commodities (cereal grains, oilseeds, nuts, spices), flour baked goods (bread, fruit cakes), pet food products, dried and fermented meat and fish products, cheeses, and high sugar products such as confectionery, dried fruit, jams and conserves (Hocking, 2001). Only a few *Penicillium* species are capable of growing below 0.80 a_w and among these are *P. brevicompactum*, *P. chrysogenum*, *P. implicatum* and other species such as *P. cinnamomipurpureum* (Hocking and Pitt, 1979; Pitt and Hocking, 2009).

Among the most commonly encountered species causing spoilage of fruit are *Penicillium italicum*, associated with the blue rot of citrus, *Penicillium digitatum* causing a devastating and rapid green rot of citrus, and *Penicillium expansum* the blue rot of apples and pears. Apart from the possibility of allergic response to the enormous numbers of dry air-borne spores produced by *P. italicum* and *P. digitatum*, especially the latter, there are no special health risks associated with these species as the rotten fruit will usually be discarded. This is not always the case with *P. expansum* that produces the mycotoxin patulin (Moss, 2008). *Aspergillus* species are both tolerant of elevated temperature and reduced a_w , and many important food spoilage species produce mycotoxins (Hocking, 2001). Some of the most xerophilic species are *A. restrictus* and *A. penicillioides*. The species most tolerant to low oxygen tensions (0.45% oxygen) is *A. candidus*.

Among the mycotoxigenic fungi, *A. flavus* and *A. parasiticus* are capable of growing at a minimum a_w of 0.80 at 30°C. In the group of the black aspergilli, *A. niger* can grow down to 0.77 a_w at 35°C. *Aspergillus ochraceus* can also grow at 0.77 a_w at 25°C while *A. versicolor* has a minimum a_w for growth of 0.78 and 0.80 (Hocking, 2001). *Penicillium* and *Aspergillus* spp. are the most common spoilage fungi, whereas *Fusarium* species are mostly responsible for significant yield losses of small grain cereals and maize (Pitt and Hocking, 2009; Quérou *et al.*, 2019). Dry foods can also be spoiled by extreme xerophiles. These fungi are those that have an absolute requirement for, rather than tolerance of, reduced a_w (Hocking, 2001). Some of the most common fungi in this category are *Bettisia fastidia*, *B. alvei*, and *Chrysosporium xerophilum*, *Xerochrysium dermatitis*, *X. xerophilum*, *Wallemia sebi* and *Xeromyces bisporus* (Pitt and Hocking, 2009; Pitt *et al.*, 2013; Rico-Munoz *et al.*, 2019).

Heat-Resistant Molds (HRM)

Spoilage of thermally processed products by heat-resistant molds (HRM) is a widespread problem for the food industries. They are responsible for the spoilage and degradation of heat-processed fruit, fruit juices and purees, and juice-containing beverages as well as teas. They can grow at low pH and low oxygen partial pressure. These molds can survive not only at temperatures applied during pasteurization, but also the high pressure used during high-pressure processing. HRM are also able to produce several mycotoxins that pose a hazard to human health (Frac *et al.*, 2015; Rico-Munoz *et al.*, 2019).

Ability of HRM to survive these elevated temperatures is due to the formation of highly heat-resistant spores called ascospores (Dijksterhuis, 2007). Thermal treatments will not prevent spoilage of products by heat-resistant molds (Evelyn and Silva, 2015; Evelyn *et al.*, 2016; Scaramuzza and Berni, 2014; Tranquillini *et al.*, 2017). Species belonging to the genera *Paecilomyces* (with byssochlamysmorph), *Aspergillus* (with neosartorya-morph) and *Talaromyces*, have been most frequently isolated from spoiled

products (Frąc *et al.*, 2015). Ascospores of the genera *Penicillium*, *Hamigera*, *Thermoascus*, *Rasamsonia* and *Monascus* are less commonly occurring. Species of the genera *Hamigera* and *Thermoascus* form ascospores that are highly heat-resistant (Rico-Munoz *et al.*, 2019).

Ascospores of HRM can be found in the ingredients (liquid and dry), packaging and the processing environment. These molds have an asexual phase, during which they produce non-heat resistant spores called conidia and a sexual phase when they produce the heat-resistant ascospores. These ascospores need a trigger such as heating or high pressure to be activated. This activation takes place during pasteurization and high-pressure processing (HPP). During activation, the thick outer layer is broken. After activation and if the conditions are favorable, the ascospore can germinate and grow, causing spoilage of the product during storage. Prevention of spoilage of heat-processed products by HRM would require reduction or elimination of the HRM ascospores contamination from raw ingredients, packaging and the processing environment (Rico-Munoz *et al.*, 2019). *Xeromyces bisporus* is able to grow at lower *aw* (0.61–0.62) than any other known organism. It produces heat-resistant ascospores and some are able to survive heating at 80°C for 10 min (Hocking, 2001; Rico-Munoz *et al.*, 2019). Ascospores of *X. bisporus* appear to be capable of surviving the baking process, leading to sporadic spoilage of baked goods, which is often not manifested until many months after production. This fungus has never been isolated from soil or decaying vegetation. The most likely sources of *Xeromyces* infections appear to be dried fruits, spices and sugary foods with low *aw* (Pitt and Hocking, 1997).

Preservative-Resistant Molds (PRM)

Preservative-resistant molds (PRM) are able to spoil products containing preservatives such as sorbic, benzoic, propionic and acetic acids and their salts (Samson *et al.*, 2004). There are two kinds of PRM: (1) the heat-resistant PRM such as *Paecilomyces variotii*, *P. niveus* (*Byssoschlamys nivea*) and *Monascus* species (*M. ruber*, *M. pilosus*) and (2) not heat-resistant ones such as *Penicillium roqueforti*, *P. paneum* and *P. carneum*, as well as conidia (non heat-resistant spores) i.e., *P. variotii*, a very common mold in the processing and packaging environment of these products (Rico-Munoz *et al.*, 2019).

The first group produce heat-resistant ascospores that are often found in ingredients such as corn flour (Rico-Munoz *et al.*, 2019). These ascospores can survive baking and pasteurization processes. The ascospores in the ingredients can also contaminate the surfaces of the equipment before the oven or pasteurizer or filler. Ascospores can then contaminate the open products and survive the heating step. These species grow better at warmer temperatures and spoilage of preserved products by these molds usually occurs during the warmer months.

A few heat-resistant fungi such as *Paecilomyces variotii* are also preservative-resistant. Some of the preservative-resistant molds such as *Penicillium roqueforti* can grow at low oxygen concentrations as well as under refrigeration (Rico-Munoz *et al.*, 2019). In the case of the second group, the non heat-resistant group, the contamination happens after the heat step given to these preserved products since they are killed by baking or pasteurization processes (Knight and Menlove, 2006; Rico-Munoz *et al.*, 2019; Tournas, 1994). Therefore, for preserved foods such as bread to become moldy, it must be contaminated either from the air, bakery surfaces, equipment, food handlers or raw ingredients after baking during the cooling, slicing or wrapping operations (Knight and Menlove, 2006; Saranraj and Geetha, 2012). In the case of the *Penicillium* species that can grow under refrigeration such as *P. roqueforti*, spoilage of these products may happen more frequently during the colder months. Fluctuation of temperature in the packaging areas must be avoided since it can result in condensation. The condensation on surfaces (walls, ceilings, overhead piping, etc.) can be conducive for mold growth. Furthermore, moisture condensation inside the package, due to packaging of the products prior to being completely cooled, may accelerate the mold growth and spoilage (Rico-Munoz *et al.*, 2019; Saranraj and Geetha, 2012).

Anaerobic Fungi

Majority of food spoilage molds have an absolute requirement of O₂ to produce adenosine triphosphate (ATP) via the oxidative phosphorylation pathway (Pitt and Hocking, 2009), although a wide diversity of mold species are able to grow under reduced O₂ partial pressure as low as 1% (Nguyen Van Long and Dantigny, 2016). Some *Penicillium* species and many other common food spoilage fungi are inhibited only slightly when grown in nitrogen atmospheres containing approximately 1.0% oxygen (Pitt and Hocking, 2009). The growth of *Mucor ambiguus* on Koji agar and *P. roqueforti* on wheat extract agar was reported at O₂ partial pressure of 0.10% (Yanai and Kojo, 1980) and 0.14% (Magan and Lacey, 1984), respectively. *Paecilomyces variotii* produced normal colonies at 25°C under 650 mm of vacuum. Most spoilage molds appear to be sensitive to high levels of carbon dioxide (Pitt and Hocking, 2009). *Paecilomyces niveus* and *Paec. fulvus* (*Byssoschlamys fulva*) were capable of growing at atmospheres containing even 60% carbon dioxide and less than 0.5% oxygen (Rico-Munoz *et al.*, 2019; Taniwaki *et al.*, 2001).

Aspergillus chevalieri and *Xeromyces bisporus* did not grow in an atmosphere of 80% CO₂ plus 20% O₂ during incubation for 60 days, or in 20% CO₂ and less than 0.5% O₂ (Taniwaki *et al.*, 2009, 2010). These atmospheres affected the viability of their spores. Neither atmosphere inhibited the growth of *Mucor plumbeus*, *Fusarium oxysporum*, *Paecilomyces fulvus*, *Paecilomyces niveus*, *Penicillium roqueforti*, *Penicillium commune* and *Aspergillus flavus*. At less than 80% CO₂ plus 20% O₂, patulin, cyclopiazonic acid and roquefortine C were produced at low levels by *Paec. niveus*, *P. commune* and *P. roqueforti*, respectively. Aflatoxin was not produced at all by *A. flavus*. *Xeromyces bisporus* was capable of growing in an atmosphere containing only 1% O₂, even in the presence of 70%–95% CO₂ but not in an atmosphere containing less than 0.5% O₂ and 20% CO₂ (Pitt and Hocking (1997)). It has been

reported that fungal growth is reduced, but rarely inhibited at CO₂ partial pressures ranging from 50% to 90% (Nguyen Van Long and Dantigny, 2016; Rico-Munoz *et al.*, 2019). Nguyen Van Long Vasseur and Couvert *et al.* (2017) confirmed that a modified atmosphere, consisting of O₂ or CO₂ partial pressure higher than 1% and 70%, respectively, was not sufficient to prevent conidial germination of the five fungal species frequently encountered as food spoilers in dairy products or, in the case of *Mucor lanceolatus* and *P. roqueforti*, utilized as cheese ripening cultures. *Mucor plumbeus*, *Fusarium oxysporum*, *Paec. fulvus*, and *Paec. niveus* are able to grow under anaerobic conditions (Pitt and Hocking, 2009; Rico-Munoz *et al.*, 2019).

Some species of *Rhizopus* and *Mucor* are frequently associated with the spoilage of fresh fruits and vegetables. *Rhizopus stolonifer* and *Mucor piriformis* are responsible for the rapid decay of soft fruits and these molds can spread rapidly, especially on commodities stored at temperatures above 20°C. *M. piriformis* has been described as a destructive pathogen of strawberries and a number of species of *Rhizopus*, especially *Rhizopus sexualis*, are pathogenic to strawberries causing a soft rot.

Psychrophilic and Psychrotolerant Fungi

Morita (1975) suggested that microorganisms that grow at 0°C or below that have an optimum temperature of 15°C and a maximum of 20°C should be called psychrophiles, while mesophilic microorganisms that grow at 0°C should be called “psychrotolerant” or “psychrotrophic” (Moyer *et al.*, 2017; Rico-Munoz *et al.*, 2019).

Microorganisms that grow at refrigeration temperatures (0–7°C) but having temperature optima above 20°C are called psychrotrophs. Psychrotrophs are defined as microorganisms that produce visible growth at 7°C ± 1°C with in 7–10 days, regardless of their optimum growth temperature. The microorganisms that are most commonly associated with refrigerated foods and cause

Coffee	<i>Aspergillus</i> , <i>Penicillium</i> , <i>Cladosporium</i> , <i>Alternaria</i> , <i>Mucor</i> , <i>Fusarium</i> , <i>Rhizopus</i> , <i>Scopulariopsis</i>	Bokhari and Aly (2009), Djossou <i>et al.</i> (2015), Kusumaningrum and Rasyidah (2019), Nganou <i>et al.</i> (2014), Rahim <i>et al.</i> (2011).

food spoilage are psychrotrophs and not psychrophiles. Psychrophiles usually die at room temperature or above. (Rico-Munoz *et al.*, 2019; Vasavada and Critzer, 2015). Psychrotolerant filamentous fungi strains of *Penicillium*, *Alternaria*, *Fusarium*, *Cladosporium* and others grow exceptionally well at low temperatures and are relevant to refrigerated foods. According to Pitt and Hocking (2009), low temperatures permissive to fungal growth lie between 7°C and 0°C for some species of *Fusarium*, *Cladosporium*, *Penicillium* and *Thamnidium* (Samson *et al.*, 2004). Although psychrophilic and psychrotolerant fungi are definitely a problem in foods preserved at low temperatures, the amount of research related to this topic is small (Geiges, 1996; Gill, 2006, 2011; Gill and Lowry, 1982). In the literature, research on species of psychrophilic fungi is rare and restricted to temperatures just above zero, although the minimum for growth is generally estimated to be at temperatures slightly below 0°C (Geiges, 1996). The minimum temperature for growth of fungi may be considerably different depending on the substrate, on which the species develops, with lower permissive temperatures when growing in food compared to a conventional culture medium.

Saccomori *et al.* (2015) reported that *Penicillium polonicum* was able to germinate forming microcolonies (about 1 mm) in 2 of 5 (40%) of the plates of culture media incubated at 0°C, whereas *P. glabrum* did not germinate at this temperature. Both species formed colonies in the first week when incubated at 5°C (Rico-Munoz *et al.*, 2019).

Yeasts and molds are able to grow in a large variety of food including raw materials such as cereals, vegetables, fruits, meat, and milk, as well as processed products (Filtenborg *et al.*, 1996). Since the first detection of fungi in food, many investigations on the natural occurrence of molds in different products have been conducted. Examples of molds contaminations in food are summarized in Table 1.

Several traditional methods, also called traditional hurdle technologies, are implemented and combined to prevent and control such contaminations. Prevention methods include good manufacturing and hygiene practices, air filtration, and decontamination systems, while control methods include inactivation treatments, temperature control, and modified atmosphere packaging (Garnier *et al.*, 2017). Preparation, packaging, and distribution could cause increased contamination. Hence including good agricultural practices, good manufacturing practices, and Hazard Analysis and Critical Control Points, should be implemented to reduce the risk of microbial contamination from farm-to-fork and to assure safe products (Jeddi *et al.*, 2014).

Mold Spoilage Assessment

To assess mold spoilage, the appropriate methodology and media must be used. While classic mycological detection methods can detect a broad range of fungi using well validated protocols, they are time consuming and results can take days or even weeks (Rico-Munoz *et al.*, 2019). New molecular detection methods are faster, but require good DNA isolation techniques, expensive equipment and may detect viable and non-viable fungi that probably will not spoil a specific product. More research is needed on the development of detection and identification methods that are both faster and highly sensitive (Rico-Munoz *et al.*, 2019). In recent years, MALDI-TOF MS has emerged as a powerful tool to identify microorganisms and has successfully been applied to the identification of filamentous fungi, especially in the clinical context (Chalupová *et al.*, 2014; Quéro *et al.*, 2019; Rico-Munoz *et al.*, 2019).

Conclusion

Mold spoilage prevention requires knowledge of the associated mycobiota on food. Control of fungal spoilage is a major concern for industrials and scientists that are looking for efficient solutions to prevent and/or limit the fungal growth or development in dairy products. Different traditional methods, also called traditional hurdle technologies, are implemented to control such contaminations including air treatment, cleaning and disinfection procedures, heat treatment, water activity reduction by brining, refrigeration, modified atmosphere packaging, as well as the use of chemical preservatives, which are considered as food additives. More research is needed on the development of detection and identification methods that are both faster and highly sensitive.

Mycobiota Causing Diseases in Pets

Do Fungi Need to Be Pathogenic?

Fungal strains (understand isolates) belonging to one species are very much close to each other in their genetic toolkit. That leads to the phenomenon the particular fungal strain as so called etiologic agent of a disease can be actually coincidental if the other members of the same species live outside the human body. Thus, in contrary to bacteria where particular strains possess so called pathogenicity islands in their genomes, and they differ among themselves in virulence and antibiotic resistance, in mycology, the pathogenicity can be attributed only to the particular species not necessarily to its every single isolate (strain) (Gräser *et al.*, 2008). Pathogenicity of fungi is a potential (virtual) behaviour of them, which might not always be displayed (Ribeiro *et al.*, 2017). On the other hand, every strain behaves very actually under given circumstances, incl. causing a disease in a host present. It even can happen that due to somehow reduced virulence (over the evolution) of human-associated infectious agents the ones with highest degree of adaptation (to humans only) can almost not cause disease. Some of the pathogenic fungi have a warm-blooded hosts different from humans.

All fungi are optimally living in their natural biotop – the niche which they are much more often isolated from in comparison to other places, so called unoptimal environments. Some species are, however, able to inhabit remarkably wide variety of environments, they have a wide ecological amplitude (Pitt and Hocking, 1997; Fortin *et al.*, 2017). This ability is based on mechanisms of conversion into a metabolically silent state (chlamydospores, endoconidia etc.) and it is polyphyletic in the kingdom Fungi. The most fungi culturable in vitro do belong to this group. Anyway, there is the large group of highly specialized fungi that require special methods for being isolated. And some of clinically important fungi are exactly such organisms.

In animal and human medical mycology, one usually posts immunocompromised patients might be invaded by any fungus practically. While even the established pathogenic fungus are, perhaps, causing disease only when being implanted into the host coincidentally as they naturally occur – grow and reproduce – in the environment. That might explain e.g., the agents of deep mycoses are not transmitted from host to host unlikely pathogenic bacteria do. Though, some fungi might have developed the ability or even a preference to use warm-blooded host bodies in some parts of their life cycle. Fungi of similar morphologies may basically differ in their optimal environment what results in absolutely different isolation rates (e.g., saprophytic *Cladosporium cladosporioides* versus pathogenic *Cladophialophora bantiana*) (Perfect, 1996).

Therefore, fungi are mostly facultative pathogens – they can be found outside the host bodies, perhaps just in a dormant state, but they are able to grow and propagulate in the animal (human) body (Pana *et al.*, 2014). Only very few species (like dimorphic fungi) – obligatory pathogens – are found exclusively on mammals. But, there are also some commensal species that complete their life cycles on the body (e.g., *Malassezia*, *Piedraia*).

Properties enabling the fungus to overcome hostile environment conditions (e.g., heat, UV radiation) are called vitality factors like content of melanin, carotenes, thick cell walls, meristematic growth. In terms of animal pathogenicity, they are non-specific. These factors alone are insufficient to cause a mycosis and they do not allow fungal adaptation to mammals (Morschhäuser *et al.*, 1996; Sterflinger *et al.*, 1999, 1998; Chechi *et al.*, 2018). Such a fungus grows on living tissue as hyphal clumps with sterile elements, and is not able to return to its normal environmental conditions anymore. Thus, it is dying with its host. The passage through the host does not have any evolutionary sense for the fungus. Selective evolutionary adaptation to the host conditions is not possible as the fungal body (thallus) is vegetative.

Anyway, there are fungi termed zoedemes which thalli in the host tissue or body fluids are actually independently propagating generations of fungal cells (e.g., yeasts with budding cells or arthroconidia, hyalohyphomycetes able to form conidia in living tissue, *Pseudallescheria* anamorph sporulating in blood). Zoedemes might be then seen as roots of evolutionary pathogenicity. The adventitious sporulation enhances invasion, like vascular penetration, so, fungus is found in blood cultures (Schiemann *et al.*, 1998; de Hoog *et al.*, 2009).

There is a dynamic balance between fungal vitality and host response: fungus wants to get optimal evolutionary fitness via maximizing reproduction and dispersion, while host needs to minimize the damage due to infection, i.e., heavy fungal growth and severe inflammation are apparent. We are speaking about pathogenic fungus. If the fungus is highly adapted to the host, it may lead to a paradox, lower virulence, and that fungus becomes adapted infectious agent, not causing infections in the end.

Dimorphic fungi have invasive zoedeme form and the hyphal environmental one. So, it is obvious some evolutionary advantage of animal association, not just the coincidental phenomenon. Apparently, the survival of the fungus will be more successful when utilizing an appropriate host. That is a sort of ecological strategy of the fungus (de Hoog *et al.*, 2009; de Moraes Gimenes Bosco *et al.*, 2019a). Virulence factors are then restricted only to properties enabling penetration and survival in living animals. We are now speaking about evolutionary pathogenesis with rather stubborn clinical picture and localization. To succeed in ecological competition with other fungi present, dimorphic fungi thus employ S- and P-strategies: S for stress-tolerance (inhabiting the unfavourable environments, deserts, shelters etc.) and P for pathogenicity, as known in *Coccidioides* or *Histoplasma* (Dix and Webster, 1995; Teixeira and Barker, 2016). The host animals serve as a reservoir of the fungus, which may hide in the infected host with properly working immune responses without causing disease but it might be dispersed from the host back into the environment. The fungus possess only a gentle virulence. If the host immune system becomes impaired (its acquired cellular

part), the fungus reactivates endogenously (Romani, 2011; Marques, 2008). The process may lead to the host death, the fungus enter to its saprobic phase and spread out of the dead body (often the case with rodent reservoirs in endemic areas of some fungi where these fungi have a continuous distribution) (Livas *et al.*, 1995; del Rocio Reyes-Montes *et al.*, 2016). *Histoplasma*'s strategy is a bit different: the fungus is environmentally occurring on animal excrements, its distribution is disjuncted. If an animal functions just as a carrier of the fungus to replace it, we speak about vector (e.g., some dermatophytes use furry animals) (Ampel, 1999). So, fungi have developed balanced strategies with known or unknown animal species where the virulence of fungus is moderate. While, human fungal infections seem to be only evolutionary dead ends.

Several hundreds of fungal species appear to be able to persist in the living animal tissue, though with the low vitality. When entering the otherwise healthy host with properly working immunity, they remain just sitting at the place of entrance (wound, airways). Innate cellular immune system of the host might be really hard working to control such an invader, thus, severe inflammation might occur. That explains chronic character of mycotic diseases. The fungus is unable to return to its common environment, that is also why it is very difficult to grow the primary culture of that fungus. From the fungal evolutionary fitness point of view, it is not a useful part, and the infection is the spill-over one (Bouhry *et al.*, 1999). In the case of immune impairment, the fungus – opportunistic pathogen – takes advantage and disseminate. Rapidly growing fungi like *Mucorales* are applying R-strategy, R for ruderal, they rapidly colonize and reproduce and disappear before other organisms enter. Fungi producing many extracellular antibiotics and toxins are working with C-strategy, C for combative, typical for aspergilli and fusaria, causing more chronic mycoses in immunocompromised hosts (Dix and Webster, 1995).

Some fungi are just a commensals on the host body, utilizing some compounds produced on the skin or its adnexes without damaging the living animal. But coincidentally, they can invade into to adjacent tissue. A typical example in animals is *Malassezia*, restricted to the vertebrate host, living from dead cells of the stratum corneum (Guillot and Bond, 1999). These species are so called autochthonous commensals as the vertebrate is their natural ecological niche. Anyway, once entering the blood stream via catheter, they are able to cause transitory fungemia. So, they might produce zoodemes, too. The fungi which are only landed on the animal body without taking any nutritional profit are stated as contaminants.

Dermatophytes might be regarded as commensals, too. They utilize keratin as the main source of carbon and nitrogen. Geo- and zoophilic *Microsporum* species do not need any living animal tissue at all. Ornamentation of their spores and fruit bodies with a lot of hairs, hooks, combs etc., allow them to remain between fur and feathers for efficient dispersion (Fig. 1). Some pathogenic species, esp. associated with humans (*Trichophyton*) are unable to produce any conidia as they propagulate only via skin scales containing infectious arthroconidia (Gräser *et al.*, 1999). Zoophilic dermatophytes on human hairless skin provoke strong inflammation followed by clearance. That process indicates a low level of adaptation of the fungus to an acquired immunity.

Faeces, dung and guano harbour plenty of fungi. Most of them are living on half-way digested products, not in the host gastrointestinal tissue. The fungi colonizing excrements are causing mycoses extremely rarely, despite of being in very close contact with the particular animal. The opposite is endosaprobe, the fungus with ecological niche inside the animal digestion tract. Typical example is *Candida* which can not survive longtime in the stool because of low competitive ability. This fungus has developed abilities to defend itself against the host reactions and against the bacteria co-present with it, establishing a delicate balance among each other (Bernhardt *et al.*, 1995; Wheat, 1995). There might be the same behaviour of *Pseudallescheria boydii* in water animals, commonly occurring in heavily organically polluted waters or in the soils very rich in nutrients (de Hoog *et al.*, 2009).

If a non-pathogenic fungus enter the host body, its immediately eradicated by the animal's unspecific cellular immunity while being fully competent. The numbers of pathogenic fungal cells first increase exponentially and with some delay further growth is controlled by acquired cellular immunity (Schaffner, 1999). Immunosuppression does not have any impact on this curve. It means, the reaction of host immune system clearly distinguish between fungal pathogens and opportunists: the first ones are capable to overcome host first, unspecific defence line. Esp. fungal species living in the vicinity of animals, being in closed confrontation with their immune system, may have developed the ways to escape the natural immunity successfully. The species

Fig. 1 *Microsporum canis* macroconidia, magnification 1,000 × easily attachable to kitten fur (with microsporidiosis).

that are primarily controlled by the acquired immunity, have reached the higher level of pathogenicity. Such species are the members of *Onygenales*, *Eurotiales* and *Chaetothyriales* according to phylogeny. These groups have acquired many of suitable vitality factors. It can be expected, there are some evolutionary “hot spots” in kingdom Fungi, where silent opportunists have developed and the genuine pathogenicity can be expected. The *Onygenales* containing several families of animal-related fungi, represent the highest level of pathogenic adaptation among the fungi known. They take profit of debilities of acquired immunity (Masclaux *et al.*, 1995; Sigler *et al.*, 2013; Antinori, 2014). The original character of their pathogenic evolution is most likely keratin assimilation. In the systemic of this order, each taxon seems to have found its specific way to modulate innate immunity.

Ecology of Pathogenic Fungi

Natural ecotops of fungal pathogens causing deep mycoses are presented in **Table 1** (de Moraes Gimenes Bosco *et al.*, 2019a; de Hoog *et al.*, 2000).

Microscopic Mycobiota Able to Cause Diseases in Pets, Incl. Captive Animals

The fungi proven to be infectious agents in companion animals upto now belong to many specific groups – archiascomycota, yeasts – asco- as well as basidiomycotic, dermatophytes, *Onygenales*, *Eurotiales* etc., as it is clear from **Table 2** (de Moraes Gimenes Bosco *et al.*, 2019a; de Hoog *et al.*, 2000; de Moraes Gimenes Bosco *et al.*, 2019b; Seyedmousavi, 2019; Ovchinnikov and Vasilyev, 2019; Moraru *et al.*, 2019; Moriello *et al.*, 2017; Schmidt, 2015; Seyedmousavi *et al.*, 2015, 2018a; Barrs and Talbot, 2014; Schwartz, 2018; Guillot *et al.*, 2018; Bosco and Bagagli, 2018; Gremiao *et al.*, 2017).

Macroorganism Histopathological Responses to Subcutaneous and Systemic (Deep) Mycoses

In the histologic mounts, specialists may encounter several typical tissue (organ) reaction pictures while being affected by pathogenic fungal growth, see **Table 3** (McKenzie, 1988).

There is also possibility to apply immunofluorescent procedures to identify fungal hyphae in the tissues affected (Thirion Delalande *et al.*, 2005) **Fig. 2**.

Human Health Risks When Working With Medically Important Fungi

According to the risk that dealing with particular fungi in the (veterinarian, medical) mycological labs might represent, mycobiota could be classified to the occupational health risk categories:

GRAS (Generally Regarded As Safe) – harmless organisms widely applied in food processing, biotechnology etc. (e.g., *Penicillium roqueforti*).

BSL-1 (BioSafety Level) – saprophytic organisms, or plant pathogens living in non-vertebrate niches, or commensals. They are able to cause superficial, uninvase or mild infection coincidentally (e.g., *Scytalidium lignicola*).

In both groups no specific occupational safety recommendations must be fulfilled.

BSL-2 – microorganisms naturally living on non-vertebrates but relatively easily able to survive in vertebrate tissue. Pathogens causing superficial infections and opportunistic pathogens belong to this group (e.g., *Aspergillus fumigatus*).

A common good laboratory praxis in the mycological laboratory must be followed. Be aware of fungi easily aerosolized, apply always sealed Petri dishes, and prefer to work in a safety cabinet.

BSL-3 – pathogens with potential to cause deep mycoses in basically healthy macroorganism (e.g., *Onygenales*).

Table 1 Niches and reservoirs of pathogenic mycobiota in the nature

Fungus	Natural environment	Animal reservoir
<i>Blastomyces dermatitidis</i>	Woods	Dogs
<i>Coccidioides immitis</i>	Desert soil	Rodents
<i>Cryptococcus neoformans</i> var. <i>neoformans</i>	Woods	Pigeons
<i>C. neoformans</i> var. <i>gattii</i>	Woods	Koalas
<i>Emmonsia parva</i>	Desert soil	Rodents
<i>Histoplasma capsulatum</i>	Bat dung, guano	?
<i>Paracoccidioides brasiliensis</i>	Woods	Armadillos
<i>Talaromyces (Penicillium) marneffei</i>	Soil	Bamboo rat
<i>Sporothrix schenckii</i>	Woods	?

Table 2 Microscopic fungi isolated as causative agents of known mycoses in pets

<i>Animal</i>	<i>Type of mycosis</i>	<i>Causative agent</i>
Dogs	Superficial – Cutaneous	<i>Malassezia pachydermatis</i> , <i>Microsporum canis</i> , <i>M. cookei</i> , <i>M. praecox</i> , <i>M. audouinii</i> , <i>M. (Nannizzia) gypseum</i> , <i>M. 	Subcutaneous – Deep	<i>Pythium insidiosum</i> , <i>Aspergillus fumigatus</i> , <i>A. niger</i> , <i>A. nidulans</i> , <i>A. versicolor</i> , <i>A. flavus</i> , <i>A. terreus</i> , <i>A. deflektus</i> , <i>A. flavipes</i> , <i>A. carneus</i> , <i>Penicillium</i> spp. (<i>verruculosum</i>), <i>Coccidioides immitis</i> , <i>Blastomyces dermatitidis</i> , <i>Histoplasma capsulatum</i> , <i>Paracoccidioides lutzii</i> , <i>Sporothrix brasiliensis</i> , <i>S. schenckii</i> , <i>Conidiobolus coronatus</i> , <i>Cryptococcus laurentii</i> , <i>C. neoformans</i> , <i>Acremonium hyalinulum</i> , <i>Bipolaris spicifera</i> , <i>Chrysosporium pannicola</i> , <i>Curvularia geniculata</i> , <i>C. lunata</i> , <i>Geomyces pannorum</i> , <i>Pseudomicrodochium suttonii</i> , <i>Scedosporium prolificans</i>
Cats	Superficial – Cutaneous	<i>Malassezia pachydermatis</i> , <i>M. sympodialis</i> , <i>M. globosa</i> , <i>M. slooffiae</i> , <i>M. nana</i> , <i>Microsporum canis</i> , <i>M. (Nannizzia) gypseum</i> , <i>M. (N.) persicolor</i> , <i>M. cookei</i> , <i>M. praecox</i> , <i>M. audouinii</i> , <i>M. gallinae</i> (<i>Arthroderma grubyi</i>), <i>Trichophyton mentagrophytes</i> , <i>T. rubrum</i> , <i>T. ronsurans</i> , <i>T. violaceum</i> , <i>T. ajelloi</i> , <i>T. terrestre</i> , <i>Epidermophyton floccosum</i>
	Subcutaneous – Deep	<i>Pythium insidiosum</i> , <i>Aspergillus felis</i> , <i>Aspergillus</i> section <i>Fumigati</i> , <i>A. udagawe</i> , <i>A. viridinutans</i> , <i>Coccidioides immitis</i> , <i>Histoplasma capsulatum</i> , <i>Sporothrix schenckii</i> s. str., <i>Bipolaris spicifera</i> , <i>Metarhizium anisopliae</i> , <i>Ochroconis humicola</i> , <i>Paecilomyces fumosoroseus</i> , <i>Staphylotrichum coccosporum</i>
Rodents (mice, voles, rats, rabbits, chinchillas, hamsters, shrews, guinea pigs, water rodents, squirrels)	Superficial – Cutaneous	<i>Trichophyton mentagrophytes</i> , <i>T. erinacei</i> , <i>Microsporum (Nannizzia) persicolor</i> , <i>M. amazonicum</i> (<i>Athroderma borellii</i>), <i>M. cookei</i> (<i>A. cajetani</i>), <i>M. gallinae</i> (<i>A. grubyi</i>), <i>M. gypseum</i>
	Subcutaneous – Deep	<i>Cryptococcus neoformans</i> , <i>Rhodotorula minuta</i> , <i>Arxiozyma telluris</i> , <i>Coccidioides immitis</i> , <i>Emmonsia crescens</i> , <i>Histoplasma capsulatum</i> , <i>Paecilomyces variotii</i> , <i>Penicillium (Talaromyces) marneffe</i>
Hedgehogs, moles	Superficial – Cutaneous	<i>Trichophyton erinacei</i> , <i>Microsporum persicolor</i>
Reptiles	Superficial – Cutaneous	<i>Chrysosporium (Nannizziopsis vriesii)</i> , <i>Ch. queenslandicum</i> , <i>Beauveria bassiana</i>
	Subcutaneous – Deep	<i>Aspergillus fumigatus</i> , <i>A. niger</i> , <i>A. terreus</i> , <i>Coniothyrium fuckelii</i> , <i>Fusarium solani</i> , <i>Ochroconis humicola</i> , <i>Paecilomyces fumosoroseus</i>
Captive birds (swans, ducklings, pigeons, chicken, parrots, toucans), mammals (dolphins, monkeys, armadillos)	Superficial – Cutaneous	<i>Piedraia hortae</i> , <i>Microsporum cookei</i> , <i>Trichophyton flavescens</i> , <i>T. simii</i>
	Subcutaneous – Deep	<i>Rhinosporidium seeberi</i> , <i>Petriella setifera</i> , <i>Aspergillus nidulans</i> , <i>A. terreus</i> , <i>Cephalophora irregularis</i> , <i>Chrysosporium tropicum</i> , <i>Coccidioides immitis</i> , <i>Curvularia geniculata</i> , <i>Histoplasma capsulatum</i> , <i>Paecilomyces variotii</i> , <i>Penicillium griseofulvum</i> , <i>Sporothrix schenckii</i>
Furry mammals	Superficial – Cutaneous	<i>Trichosporon asahii</i>
Fishes	Subcutaneous – Deep	<i>Ochroconis humicola</i> , <i>Sporothrix schenckii</i>
Insects	Cutaneous – Deep	<i>Ophiostoma stenoceras</i> , <i>Beauveria bassiana</i>

All laboratory handling must be carried out in the safety cabinet equipped with HEPA filters, without recirculation, that is used exclusively just for the BSL-3 fungi. Complete decontamination of the work place and room must be performed after the work. Fungal cultures should be kept in test tubes, not on agar plates (Sugui *et al.*, 2014).

Serological Methods to Diagnose Systemic Mycoses (de Moraes Gimenes Bosco *et al.*, 2019b; Seyedmousavi, 2019; Barrs *et al.*, 2015)

In animal serum samples antibodies against the particular mycotic agent might be detected by mean of several methods. The oldest employed immunodiffusion assay, relative inexpensive and easy-to-perform but also of low sensitivity, has been overcome by ELISA and Western blot providing high sensitivity and specificity. More rapid tests are hemagglutination assay, also lacking high

Table 3 Typical deep mycosis markers present in histologic mounts from biological specimens

Mycosis	Histological picture				
	Purulence	Granuloma	Fibrosis	Necrosis	Other
Phaeohyphomycosis	–	+	–	–, w	0
Mycetoma	+	+	+	+	Sinus tract grains
Chromoblastomycosis	–	+	+	–	Hyperkeratosis, acantosis
Sporotrichosis	+	+	+	+	Asteroid bodies
Aspergillosis	+	+	–	+	0
Blastomycosis	+	+	+	–	0
Paracoccidioidomycosis	+	+	+	+	0
Coccidioidomycosis	+	+	+	–	0
Histoplasmosis	–	+	+	–	Calcifications, coin lesions
Zygomycosis (Fig. 2)	+	–	–	+	Oedema
Entomophthoromycosis	–	+	+	–	Oedema
Yeast infection (<i>Candida</i>)	+	+	–	+	0
Cryptococcosis	–	+	–	–	0

Source: W – weak, 0 – nothing observed.

**Fig. 2** Histological picture of invasive zygomycosis in sinuses. Courtesy of the histological lab of the Slovak Medical University in Bratislava.**Table 4** Antimycotics used in treatment of mycoses in social animals

Mycosis	Antimycotic
<i>Pythium</i> infections	Mefenoxam (agricultural fungicide), potassium iodide, terbinafine, itraconazole (immunotherapy with macerated fungal hyphae, photodynamic therapy, vaccination)
Superficial-Cutaneous	Lime sulphur, chlorhexidine, Insecticide lufenuron, nystatin, griseofulvin, miconazole, ketoconazole, enilconazole, itraconazole, posaconazole, terbinafin (comb. with antibiotics and glucocorticoids)
Subcutaneous-Deep	Amphotericin B, clotrimazole, miconazole, enilconazole, ketoconazole, fluconazole, itraconazole, voriconazole, posaconazole (emerging azole resistant yeasts, aspergilla) (Seyedmousavi <i>et al.</i> (2018b); Talbott <i>et al.</i> (2015))

level of sensitivity and specificity, and immunochromatography, efficient as well as rapid and convenient analytical method employed recently to confirm fungal deep fungal infection. To confirm the fungal infectious agent antigens in serum or tissue, that another promising methodic approach, successfully used e.g., *Aspergillus* galactomannan detected by ELISA.

Antifungal Therapy Applicable in Pets' Treatment

An overview of commonly administered antifungals in veterinary medicine is given in Table 4.

Chemical disinfectants are applicable topically (Zur and Elad, 2006), antimycotic drugs either topically (ointments, creams/lotions, liquids, baths) or systemically (Sim, 2016). The particular therapy is often combined with surgical removing of the affected lesion cutaneous or inside the animal body. In some diseases, successful vaccination measures are of value, e.g., against pythiosis in dogs, or experimental phototherapy (Singh and Srivastava, 2019; Mendoza *et al.*, 2003; Pires *et al.*, 2014).

Conclusion

Just a very few representatives of fungal microorganisms might be stated as true pathogens. They developed some specific strategies enabling them exploit living animals to spread themselves in their natural inhabitat. The particular animals, usually living in endemic areas of such fungi, serve as reservoirs without showing any symptoms of a mycosis. Other fungi, so called opportunistic pathogens co-exist with their animal hosts in a delicate dynamic balance with the primary target not to kill the animal. Anyway, esp. companion animals and the captive ones might show relatively high degree of sensitivity to fungal diseases, incl. the systemic mycoses, even with fatal outcome possibility. Once the animal living with humans is taken from very different natural conditions to somebody's house, it become vulnerable and prone to infectious diseases (reptiles, fishes, exotic birds or mammals) much more. On the other hand, many pathogens are crossing from animals to humans, and are able to spread quickly to new places. Though, recently taken into account mostly with viruses, the behaviour might be obvious in fungi as well, and those originated in animals continue to evolve and at some point could pose a threat to humans. Especially, the anthropogenic changes of the nature worldwide drive the emerging of new zoonotic diseases in humans as is the concept of planetary health, new scientific discipline. In the case of diseases in companion animals and pets, due to really close contact with humans, mostly children as well, the crossing pathogens must be taken very seriously as a part of preventive measures in human medicine, too (Vidal, 2020). The fungi isolated as causative agents of mycoses should be handled precautionary in the diagnostic lab. Animal mycoses of different localizations on the bodies can be treated with the same antimycotics which are nowadays applied in human medicine as well.

Potential Conflict of Interest

The publication resulted from the project realization “Centre of Excellence in the Environmental Health”, ITMS Nr. 24240120033, financially supported by the EU Structural Fund on Regional Development, operation program Research and Development.

Production of Native and Recombinant Enzymes by Fungi for Industrial Applications

Jean-Paul Ouedraogo and Adrian Tsang, Concordia University, Montreal, QC, Canada

© 2021 Elsevier Inc. All rights reserved.

Introduction

Enzymes are biological catalysts that accelerate chemical reactions with high efficiency and specificity (Robinson, 2015). Almost all enzymes are protein in nature, with the exception of catalytic RNA molecules (ribozymes) that play an important role in gene expression (Robinson, 2015). Also known as biocatalysts, enzymes mediate metabolic processes in living organisms (microorganisms, plant, animals, and humans) to occur at rates fast enough to sustain life. For example, Radzicka and Wolfenden (1995) estimated that orotidine 5'-monophosphate decarboxylase, an enzyme involved in nucleic acid metabolism, accelerates the decarboxylation of orotic acid reaction rate by 17 orders of magnitude, indicating that the catalytic effect of enzymes is vital for living organism. The capacity of enzymes to reduce process time and its low energy requirement has gained interest in industry.

Centuries before their biotechnological exploitation, enzymes derived from living organisms had unknowingly been used for food and alcohol production. For example, the conversion of grains and fruits to alcohol is mediated by enzymes produced by fermenting yeasts (Ray *et al.*, 2016). Attempts to extract the active agent in milk coagulation for cheese production had led to the direct use of enzymes in industrial processes. In 1874 the Danish chemist Christian Hansen used rennet extracted from calf stomach for commercial cheese production (Abdel-Fattah and Mabrouk, 1972). The late nineteenth century also witnessed the first documented use of fungal enzymes in an industrial process. Jokichi Takamine developed a method of production and extraction of amylase used for malting in brewing (Robinson, 2015; Bennett, 1998). Today, enzymes are widely used in industries including food, detergents, agriculture, chemicals, pharmaceuticals, textile and fuel (Adrio and Demain, 2014; Meyer *et al.*, 2011). There are more than 3000 different enzymes (intra and extracellular) known but only 5% (mostly extracellular) are commercially used (Marzo *et al.*, 2019; Green and Beezhold, 2011; Schwab, 2002), and over 500 commercial products worldwide are processed using enzymes (Thapa *et al.*, 2019). The enzyme global market is expected to grow at a compound annual growth rate of 6.83% during the forecast period of 2019–2024 (Kunal and Amit, 2019). Up until the 1970s, industrial enzymes were mainly produced by animals and plants. Owing to their economic, technical and/or ethical advantages over plants and animals, microorganisms are currently the preferred hosts for producing industrial enzymes. Among microorganisms used for industrial enzymes production, fungi are frequently used for producing heterologous proteins and for eukaryotic enzymes that require posttranslational modifications to be functional (Nevalainen and Peterson, 2014). This is because bacteria do not have the posttranslational modification machinery found in eukaryotes. The high degree of nutritional flexibility, metabolic versatility and the ability to produce large quantity of extracellular enzymes have made fungi the preferred hosts for the industrial production of native enzymes as well as recombinant enzymes from endogenous and heterologous organisms. Moreover, enzymes and organic acids produced by fungal species of genera such as *Aspergillus*, *Mucor*, *Rhizopus*, *Trichoderma*, *Penicillium*, *Pichia*, and *Saccharomyces* have received the GRAS (Generally Recognized As Safe) status from the Food and Drug Administration of the United States, allowing their broad use in different industrial sectors, including food and pharmaceutical industries. With recent advances in molecular genetics and genome editing, and the availability of genomic and proteomic tools, the production of recombinant enzymes has been expanded. About 90% of industrial enzymes are produced as recombinant proteins (Lara-Marquez *et al.*, 2011; Adrio and Demain, 2014). Described here is the production of native and recombinant enzymes by fungi for different industrial sectors.

Fungal Hosts for Industrial Enzyme Production

The use of fungal enzymes to convert and produce fermented foods and beverages such as bread, cheese, wine and beer, dates back centuries (Cairns *et al.*, 2018). Currently, the fungi that produce the majority of industrial enzymes of fungal origin come from a limited number of genera of which *Aspergillus* and *Trichoderma* species predominate (Frisvad *et al.*, 2018). The production organisms should preferably have a history of producing products that have received the GRAS status (US Food and Drug Administration, 2019), which means that they are known to be non-pathogenic and they do not produce metabolites that could be harmful to human and animals. This is especially important when the enzyme is used in food or drug applications. In addition to safe production, at least two other criteria need to be taken into consideration in selecting an industrial enzyme producer for development: (1) The capacity of the fungus to secrete large quantities of enzymes to the cell exterior to facilitate downstream processing; and (2) genetic tractability for production of recombinant enzymes. Fungi that are amenable to CRISPR genome-editing technology would have both short- and long-term advantages in strain development. *Aspergillus* species (e.g., *A. niger*, *A. oryzae*) and *Trichoderma reesei* have the above mentioned features and are used in industry for the production of extracellular enzymes such as alpha-amylases, glucoamylases, cellulases, pectinases, xylanases, and proteases (Frisvad *et al.*, 2018).

Table 1 List of important commercial fungal enzymes

Enzyme	Source	Action	Sector application ^a
α -Amylase	<i>A. niger</i> , <i>A. oryzae</i>	Starch hydrolysis	Food, technical
α -Galactosidase	<i>A. niger</i> , <i>A. oryzae</i> , <i>T. reesei</i>	Remove terminal α -galactosyl moieties from polysaccharides	Food, technical
α -Glucosidase	<i>A. niger</i> , <i>A. oryzae</i> , <i>P. chrysogenum</i> , <i>T. reesei</i>	Hydrolysis of starch dextrin to glucose	Food, feed, technical
Aminopeptidase	<i>A. niger</i> , <i>A. oryzae</i> , <i>R. oryzae</i>	Releases amino acids from N-terminal of proteins and peptides	Food, technical
Arabinofuranosidase	<i>A. niger</i>	Hydrolysis of non-reducing arabinofuranosyl from arabinan	Food
β -Glucosidase	<i>A. niger</i> , <i>P. decumbens</i> , <i>P. multicolor</i>	Releases glucose from oligosaccharides of cellulose	Food, feed, technical
Catalase	<i>A. niger</i>	Converts hydrogen peroxide to water and oxygen	Food, technical
Cellulase	<i>A. niger</i> , <i>P. funiculosum</i> , <i>Rasamonia emersonii</i> , <i>T. reesei</i> , <i>T. viride</i>	Hydrolysis of plant cell wall cellulose to oligosaccharides	Food, feed, technical
Dextranase	<i>P. funiculosum</i>	Endohydrolysis of D-glucosidic linkages in dextran	Food
Glucoamylase	<i>A. niger</i> , <i>R. delemar</i> , <i>R. oryzae</i>	Starch hydrolysis	Food, technical
Glucose oxidase	<i>A. niger</i> , <i>P. chrysogenum</i>	Oxidizes glucose to gluconic acid	Food, feed, technical
Hemicellulase	<i>A. niger</i> , <i>T. reesei</i> , <i>T. longibrachiatum</i>	Hydrolysis of plant cell wall hemicellulose to oligosaccharides	Food, feed, technical
Laccase	<i>A. oryzae</i> , <i>T. reesei</i> , <i>Trametes hirsuta</i>	Oxidize phenolic substrates	Food, technical
Mannanase	<i>A. niger</i> , <i>T. reesei</i>	Hydrolysis of mannan from lignocellulose	Food, feed
Pectinases	<i>A. niger</i>	Hydrolyzes pectin	Food, technical
Pectinesterase	<i>A. niger</i>	Catalyzes de-esterification of methoxyl group of pectin	Food, feed
Phytase	<i>A. niger</i> , <i>A. oryzae</i>	Hydrolysis of phytic acid to release phosphorus	Food, technical
Lipase	<i>R. oryzae</i> , <i>R. delemar</i> , <i>R. niveus</i> , <i>A. niger</i> , <i>A. oryzae</i>	Hydrolyzes triacylglycerols to glycerol	Food, technical
Proteases	<i>A. oryzae</i> , <i>A. niger</i>	Hydrolyzes proteins	Food
Xylanase	<i>A. oryzae</i> , <i>A. niger</i> , <i>T. reesei</i>	Hydrolyzes polysaccharide xylan into xylose	Food, feed, technical

^aTechnical refer to enzymes used in detergents, textile, leather, pulp and paper industries, synthesis of organics and production of biofuels.

Aspergillus

The genus *Aspergillus* comprises ~350 species. Two particular species, *A. niger* and *A. oryzae* are widely used in industry for their native enzymes (Berka *et al.*, 1992; Mekala *et al.*, 2008; Pandey *et al.*, 2018). They produce broad range of enzymes related to degradation of storage polysaccharides, including starch and inulin (de Vries and Visser, 2001; Wang *et al.*, 2020), as well as plant cell wall components, such as xylan, xyloglucan, cellulose, galactomannan and pectin (de Vries and Visser, 2001).

The decomposition capacity of polysaccharides has made *Aspergillus* an important cell factory for the enzyme producing industry. Enzymes from *Aspergillus* are used in diverse applications such as brewing, cheese manufacturing, wine modification, food preservation, starch degradation, juice clarification and animal feed additives. Enzymes from *Aspergillus* have limitations in processes requiring alkaline pH such as in detergents or high temperature (above 60°C) as in starch liquefaction. This may be because *A. niger* and *A. oryzae* have been evolved to thrive in acidic environment at temperatures around 30°C, and enzymes produced by them tend to have acidic pH optimum and temperature optimum below 60°C (Murphy *et al.*, 2012; Strasser *et al.*, 2015).

The industrial exploitation of *Aspergillus* started in 1894 with the patent of Takamine on the production of alpha-amylase from *A. oryzae* (Takamine, 1914). Since then different fermentation techniques have been employed for the industrial production of amylases. An optimized *A. niger* strain can produce over 40 g L⁻¹ of alpha-amylase, and this can be further improved with recombinant DNA technologies (Wang *et al.*, 2016).

Trichoderma

The species of the genus *Trichoderma* are ubiquitous filamentous ascomycetes. *T. reesei* is the best-known species of the genus used in industry. The enzymatic secretion potential of *T. reesei* (*Hypocrea jecorina*) was discovered during the Second World War when the fungus destroyed the US Army equipment on the Solomon Islands. Researchers have exploited this decomposition potential to screen fungi from the Solomon Islands for their ability to degrade native crystalline cellulose. The strain of *T. reesei* designated QM6a was shown to possess the highest ability to break down cellulose and it had become the starting strain for developing hyper-producers of cellulases and hemicellulases (Bischof *et al.*, 2016). Generations of random mutagenesis of *T. reesei* QM6a have resulted in strains that hyper-produce cellulolytic enzymes; among them strain RUT-C30, a fourth-generation mutant, is able to produce about 20 g L⁻¹ of extracellular protein and displayed cellulase activity of 15 filter paper units mL⁻¹ under controlled fermentation conditions (Peterson and Nevalainen, 2012). Strains derived from *T. reesei* are considered benchmark organisms for the production of industrial cellulolytic enzymes.

Other fungi used for industrial enzymes production include species of *Saccharomyces*, *Rhizopus*, *Fusarium*, *Penicillium*, *Pichia*, *Candida*, *Mucor*, *Rhizomucor*, *Rhizopus*, *Disporotrichum* and *Humicola* (Bennett, 1998; Nevalainen *et al.*, 2005). Table 1 summarizes the major enzymes used in industries and their production hosts.

Fermentation Technologies for Fungal Enzymes Production

Fermentation is a metabolic process that produces chemical change in organic substrates through the action of enzymes that are produced by a growing microorganism. In contrast to yeast and bacterial cells in which the division is planktonic, filamentous fungi grow by forming new cells at the tip of existing hyphae where they can form branches. The branches can grow into either elongated hyphae or clump together with neighboring branches into pellets, making fermentation of filamentous fungi challenging. Two main methods of fermentation, solid-state fermentation and submerged fermentation have been developed to adapt the different morphologies and natural habitats of fungi.

Solid-State Fermentation

Solid-state fermentation is known as the oldest fermentation technology and takes place in the absence or near absence of free water in a solid matrix that contains enough moisture to support the activity of the microorganisms (Lekha and Lonsane, 1997; Sugai-guerios *et al.*, 2015). This fermentation process mimics the natural environment of the microorganisms, especially for filamentous fungi, thus promoting high productivity. Solid-state fermentation has been used for the production of fermented food such as Koji with *A. oryzae* and for cheese making with *Penicillium roqueforti* (Ashok, 1992). However, technical limitations reduce the use of solid-state fermentation in industrial sectors at large scale. One of these limitations is to define the proper substrate for fermentation, the selection of which depends on the adherence capacity of the microorganism being used to produce the enzyme and its requirement of water activity. Adherence property and the requirement of water activity are dependent on the physiological characteristic of the microorganisms. Microorganisms with a higher water activity requirement, such as bacteria, have difficulty to perform in solid-state fermentation. Most solid-state fermentations used in the enzyme industry are based on fungi as the native producers and are not used in the production of recombinant enzymes. This technique of fermentation mimics the natural habitat of the filamentous fungi far better than submerged cultivation and may explain their high productivity. The fungal filaments in solid-state fermentation favor high penetration into the substrates and have high osmotic tolerance compared to bacteria and other single-cell microorganisms (Ashok, 1992). However, the disadvantage of solid-state fermentation is the scale-up from laboratory to commercial production (Dulf *et al.*, 2019). This is due to the large size of inoculum and surface areas that are needed for commercial production. With large inoculum size, the aeration and agitation needed for the control of parameters such as pH and temperature become difficult as they disturb the fermentation process. In addition, the recovery of the final product (enzyme) from the solid substrate at larger scale is complex and labor intensive. These shortcomings have reduced the application of solid state fermentation in commercial enzymes production and limited its use to bioremediation, bioleaching, biobenefication and biopulping (Arora *et al.*, 2018). In these cited industrial sectors, solid-state fermentation has the advantage of being economical (no water or less water requirement and use of raw, inexpensive material as substrate).

Submerged Fermentation

Submerged fermentation is a method of cultivating microorganisms in liquid nutrient media. For industrial production, this implies growing the selected microorganism in closed vessels, called bioreactors, which contain nutrient broths. The system design for bioreactors allows supply of oxygen as required for aerobic microorganisms and the ability to monitor and control different parameters such as pH, temperature, viscosity, dissolved oxygen, foam formation, biomass formation, substrate utilization and desired product formation (Liu *et al.*, 2019; Xiong *et al.*, 2012). The ability to control parameters online has facilitated the use of submerged fermentation where fermentation takes place in large fermenters with volumes that vary from thousands to hundred-thousand liters (Liu *et al.*, 2019; Xiong *et al.*, 2012). For example, 90% of commercial xylanases are produced using submerged fermentation (Polizeli *et al.*, 2005). Fungal submerged fermentation is often associated with high viscosity of the culture broth, which limits oxygen and mass transfer, and can affect enzyme production. However, this limitation can be reduced or eliminated with the implementation of different submerged fermentation processes. There are four types of submerged fermentation processes: batch culture, fed batch culture, continuous culture and perfusion batch culture.

Batch cultivation is the simplest mode of operation, in which the microorganisms are inoculated in fixed volume of fermentation medium for a defined time, after which the broth is collected for downstream processing. In fed batch process mode, concentrated components of the nutrients are gradually added to the batch culture. In continuous reactors, fresh medium is continuously added and broth from the bioreactor is continuously withdrawn. This allows the fermentation process to be operated for long periods. In the perfusion batch cultivation mode, there is an equal volume of addition of new medium and withdrawal of cell free broth. Each type of submerged fermentation process has advantages and disadvantages, and their use depends on the end-use of the production and the type of microorganism that is being used. For example, continuous reactors can be more productive

Fig. 1 Host and Origin of industrial enzymes. (a) Host for industrial enzyme production, (b) Origin of industrial enzymes. *Referred to mammalian or unknown. Reproduced from AMFEP, 2015. List of Commercial Enzymes. Available at: https://amfep.org/_library/_files/Amfep_List_of_Enzymes_update_May_2015.pdf. (Accessed January 2021).

than batch reactor and can reduce the viscosity for fungal cultivation; however the long fermentation time in the continuous process increases the risk of contamination. Submerged fermentation is more commonly used in industrial fermentation than solid-state fermentation for enzyme production due to its ability to control the fermentation parameters using defined substrates. However submerged fermentation is not practical for complex substrates such as agricultural, forestry, and food processing residues and wastes. These complex substrates need to be first processed before use by the microorganism in the bioreactors.

Application of Fungal Enzymes

Fungal enzymes have revolutionized the biotechnology industry due to their functionalities, applications, low environmental impact, biodegradability and cost effectiveness. Enzymatic processes have become preferred alternatives to chemical process. The increased research and development activity within the enzyme industry and academic laboratories is the driving force behind the market expansion (BCC, 2020). Fungal enzymes are used in industrial sectors (pharmaceutical, agricultural, food, feedstuff, cosmetics, detergent, textile, waste treatment, petroleum) as processing aids for the production of numerous products. For example, cheese, milk, yogurt, bread, cookies, fruit juice, beer, wine and meat are food products that are frequently processed with enzymes such as alpha-amylase, alpha-glucosidase, glucose oxidase, cellulases, xylanases, pectinases, proteases and lipases (Kumar and Satyanarayana, 2013; Damasio *et al.*, 2019; Ding *et al.*, 2019). The main application of enzymes in food industry is starch conversion to generate ingredients for foodstuffs. In addition, enzymes in this sector are also used to improve food flavor, texture, digestibility and the nutritional value (Kumar and Satyanarayana, 2013; Damasio *et al.*, 2019; Ding *et al.*, 2019).

Enzymes play an important role in animal nutrition and their use in this sector is expected to grow, especially for swine and poultry nutrition (BCC, 2020). The main purpose of using enzymes in feed is to improve digestibility to lessen production cost and reduce the environmental footprint (Gupta *et al.*, 2015). Enzymes such as phytases, beta-galactosidases, glucanases, xylanases, alpha-amylases and polygalacturonases are used in the feed industry (Caballero *et al.*, 2007; Walsh *et al.*, 1993). Their addition to animal feed is important for animal growth and nutrition, and the global market of these enzymes is increasing due to the increased demand for meat products. For example, the use of phytases to release phosphorous from phytate found in feed has two benefits by reducing the use of expensive inorganic phosphorus in animal diets and the environment pollution caused by excessive manure phosphorus runoff (Bohn *et al.*, 2008).

Besides their application in food and feed industries, the medical uses of enzymes notably include digestive aids with amylases, proteases and lipases (Ianiro *et al.*, 2016), anti-clotting with urokinase (serine protease) and streptokinases as fibrinolytic and thrombolytic agents (Kumar and Singh, 2004; Tharwat, 2006), and for diagnosis purpose with glucose oxidase along with peroxidase to detect the glucose level (Cherry *et al.*, 1999; Dubey *et al.*, 2017). In this area of enzyme applications, recombinant heterologous enzymes are often involved.

Enzymes used in cosmetics include among others proteinases for dermatological use and superoxide dismutase in anti-aging formula due to its protective action against oxidative stress (BCC, 2020).

Technical enzymes are used in detergents, textile, leather, pulp, paper, organics synthesis and biofuels production. The main technical enzymes are amylases, proteases, lipases, cellulases, xylanases and catalases. The important properties of technical enzymes are the ability to act at broad range of temperature and pH. For example, biofuels production would benefit from enzymes that are active at > 60°C for hours (reduced the risk of contamination and accelerate reaction time) whereas in detergents value can be gained from enzymes that are active at cold temperature (reduced energy input and preservation of fabrics integrity) and alkaline pH.

About 60% of commercial enzymes reported in 2015 are produced using fungi as hosts (Fig. 1(a)). Among the fungal production hosts, *Aspergillus* sp. are most often used (46%), followed by *Trichoderma* sp. (20%) and *Penicillium* sp. (8%) (AMFEP,

2015). In addition, among known enzymes of fungal origin, most of the native and recombinant enzymes produced are from *Aspergillus* sp. (Table 1, Fig. 1(b)). Therefore, fungi are both the predominant source of current industrial enzymes produced and the main hosts used for their production.

Commercial Native Enzymes From Fungi

Amylases

Fungal amylases as a group represent one of the main enzymes used in industry (De Souza and De Oliveira, 2010; Singh *et al.*, 2014). Alpha- and beta-amylases catalyze the hydrolysis of starch into sugars and are broadly applied in industries. Their fields of application include pharmaceutical, food, detergent, textile and biofuel industry. Alpha-amylase is an endo-1,4- α -D-glucanoglucosylhydrolase that randomly cleaves the 1,4- α -D-glycosidic linkages between adjacent glucose units in the amylose chain (Ray, 2004; Roth *et al.*, 2019; van Lanen and LeMense, 1946; De Castro *et al.*, 2010). Beta-amylase produces maltose from starch by hydrolyzing the α -1,4-glucan linkages (Ray, 2004). Alpha-amylase from *A. oryzae* was the first microbial enzyme to be manufactured and solid-state fermentation was initially used (Bogar *et al.*, 2002; Rahardjo *et al.*, 2005). To improve productivity, the manufacture of amylases now uses submerged fermentation with *A. oryzae* and *A. niger* as the main producers. Fungal amylases, particularly those from *A. niger* have a good tolerance to low pH (Varalakshmi *et al.*, 2009; Shenolikar and Stevenson, 1982). The *A. niger* genome harbors multiple genes encoding alpha-amylases (Pel *et al.*, 2007) and the major secreted alpha-amylase has an optimal pH of 3.2–3.5. The acid alpha-amylase is known to be suitable for saccharification of starch at pH 3.5–4.0 in combination with the *A. niger* alpha-glucosidase (Shenolikar and Stevenson, 1982; Takagi *et al.*, 1969; Tokhadze *et al.*, 1975).

Proteases

Proteases (endopeptidases and exopeptidases) are a large group of enzymes that hydrolyze the peptide bonds of proteins. The endopeptidases act preferentially on peptide bonds in the inner regions of the polypeptide chain whereas exopeptidases act near the ends of the polypeptide chain. Depending on their site of action at the amino- or carboxyl-terminal of the polypeptide, they are classified as aminopeptidases or carboxypeptidases, respectively (Sabotic and Kos, 2012). Carboxypeptidases can be divided into serine peptidases, cysteine peptidases and metallopeptidases based on their active site amino acid residues or requirement for metal ions for activity. In the same manner, endopeptidases comprise serine proteases, aspartic proteases, cysteine proteases and metalloproteases (Rao *et al.*, 1998).

Proteases are used in industrial processes including detergents, textiles, leather, cheese production, baking, beer preservation, and meat tenderization (Kang *et al.*, 2014; De Souza *et al.*, 2015; Sullivan and Calkins, 2010; Vishwanatha *et al.*, 2010). They are also used in the pharmaceutical industry and represent about 60% of the total enzyme market (Mordor and Intelligence, 2018).

Xylanases

Xylanases are a group of enzymes that depolymerize xylan, the second most abundant plant cell wall polysaccharide, to xylose. Multiple enzymes are involved in the hydrolysis of xylan and they include endoxylanase, beta-xylosidase, alpha-glucuronidase, alpha-arabinofuranosidase and acetylxylanesterase (Juturu and Wu, 2012). The principal commercial sources of xylanases among mesophilic filamentous fungi are *Aspergillus* sp. and *Trichoderma* sp. The need for xylanases with a greater range of pH and temperature tolerance has directed effort for the research on xylanases producers among thermophilic fungi and bacteria (Lasa and Berenguer, 1993; Bruins *et al.*, 2001).

Submerged fermentation is the preferred method of manufacturing xylanases. However, about 10% of xylanases production is performed using solid-state fermentation (Polizeli *et al.*, 2005), which takes advantage of using cheap complex substrates, such as underutilized agricultural products, food processing wastes and forestry residues, as carbon sources. In addition, co-cultivation of different fungal xylanase producers can be used to boost the production titer. For example, a mixed culture of *T. reesei*, *A. niger* and *A. phoenicis* using solid-state fermentation has been reported to produce 2800 U g⁻¹ of xylanases (Gutierrez-Correa and Tengerdly, 1998).

Pectinases

Pectinases are enzymes that break down pectin, a polysaccharide found in plant cell walls. Also known as pectic enzymes, pectinases are classified in three groups: the hydrolases that hydrolyze the glycosidic bonds of pectic acid (also known as polygalacturonic acid), the lyases that degrade pectic acid through an elimination reaction, and esterases that cleave the methyl ester bonds in pectin. The commercial pectinases are mixtures of these three types of enzyme activities. For economical and functionality reasons, microbial source of pectinases represents 90% of industrial pectinases. Filamentous fungi including *A. niger*, *A. oryzae*, *Aspergillus awamori*, *Aspergillus sojae*, *Aspergillus carbonarius* and *Trichoderma* sp. are known producers of pectinases with *A. niger* as the major commercial producer (Blandino *et al.*, 2001). Due to the importance of pectinases in food industry, they represent almost 25% of the global food enzyme market (Ruiz *et al.*, 2012). Pectinases are used for extraction and clarification of fruits juice and wine, textile and plant fiber processing, tea, coffee and oil extraction (Da Silva *et al.*, 2005).

Glucose Oxidase and Catalase

Glucose oxidase is abundantly produced by *A. niger* and *Penicillium chrysogenum*. Traditionally, solid-state fermentation and submerged fermentation of strain NRRL3 of *A. niger* (ATCC 9029) is the common source for the commercial glucose oxidase (Crueger and Crueger, 1990; Dubey *et al.*, 2017). However, submerged fermentation has been found to be more effective for production due to the ability to control the cultivation parameters of the technology (Dubey *et al.*, 2017). Glucose oxidase converts β -D-glucose to D-gluconolactone and hydrogen peroxide by oxidation (Primo-Martin *et al.*, 2003). D-gluconolactone is further hydrolyzed to gluconic acid. The application of glucose oxidase is mainly in food industry. The enzyme is used in baking industry for improving dough texture. Glucose oxidase is thought to possess antioxidant properties that preserve the taste and flavor of wine and beer. The antimicrobial (antibacterial and antifungal) activity mediated by glucose oxidase is exploited as preservative for milk and dairy products. However, this attributed property is dependent of the amount of catalase that is usually co-produced in the host strain. The antimicrobial action has been suggested to be primarily based on the release of hydrogen peroxide by glucose oxidase, but the presence of catalase converts hydrogen peroxide to oxygen and water (Fuglsang *et al.*, 1995). The catalase activity is exploited for textile enhancement and in various food processing (Tzanov *et al.*, 2002). For most large-scale applications, the enzymatic activities of glucose oxidase and catalase are not separated. Both may be used together to avoid net hydrogen peroxide production.

Cellulases

Cellulose is the principal component of plant cell wall and the most abundant renewable polymer on the planet. A coordinated action of multiple enzymes endoglucanases, exoglucanases, cellobiohydrolases and beta-glucosidases collectively called cellulases is required for efficient degradation of cellulose. They hydrolyze the glycosidic bonds in cellulose to release glucose (Berg *et al.*, 1988; Tomme *et al.*, 1988).

The major industrial fungal cellulases producer is *T. reesei* (Irwin *et al.*, 1993). *Trichoderma* cellulolytic enzymes are known for acting simultaneously in a synergistic manner (Reese, 1956). In addition to *T. reesei*, *Aspergillus* sp. are used for industrial cellulases production. For a complete overview of cellulases produced by *T. reesei* and *Aspergillus* sp., the reader is referred to the review of Payne *et al.* (2015).

Glucoamylase

Also known as glucan 1,4- α -glucosidase, amyloglucosidase, exo-1,4- α -glucosidase, and 1,4- α -D-glucanglucohydrolase, Glucoamylase hydrolyzes from non-reducing ends of amylose and amylopectin to glucose monomers. Glucoamylases can also cleave the 1,6- α -linkages at the branching points of amylopectin (Manjunath *et al.*, 1983). The major source of glucoamylase comes from *A. niger*. In addition, *A. awamori* and *Rhizopus* sp. are industrially used for glucoamylase production (Silveira *et al.*, 2006; Anto *et al.*, 2006). Glucoamylase together with the other amylolytic enzymes such as alpha-amylases are used in biorefineries for their capacity to liquefy starch. In addition, glucoamylase is used in the production of glucose that serves as feedstock for fermentations and in the production of high fructose sirups. It is also the key enzyme in Sake and soy sauce production. Since the production capacity of *A. niger* glucoamylase is dependent of the medium and cultivation condition and the glucoamylase market is competitive, there is continuous development in the optimization of the production method along with genetic engineering of the producing strains.

Commercial Heterologous Enzymes From Fungi

The production of fungal enzymes from native sources sometimes cannot meet the increasing market demand due to their low yields or to the high cost of the industrial fermentation processes. Recombinant enzyme production in easily cultivable and genetically tractable hosts with higher production yield can allow reduction of the costs of production. The capability of filamentous fungi to grow in a broad range of substrates, to produce large amounts of enzymes and the availability of their eukaryotic post-translational protein modification machinery make them attractive hosts for heterologous enzyme production from different sources. In addition, the availability of genome sequences and genetic engineering tools has increased heterologous enzyme production in fungi. Heterologous enzyme productivity can be increased by inserting multiple copies of target genes into the host organism, use of strong promoters, and efficient signal peptide sequence for extracellular secretion. Another advantage of heterologous protein production is the possibility to commercialize an enzyme from a toxin-producing organism by transferring the encoding gene into a safe fungal host (Piscitelli *et al.*, 2010). Although heterologous fungal enzymes can be efficiently produced, production of gene products from exogenous organisms can still result in low production yields due to poorly understood factors including protein mis-folding. For example, production levels of thermophilic bacterial xylanases in *T. reesei* have remained considerably low at about 100 mg L⁻¹ even after expression optimization (Te'o *et al.*, 2000).

Genetic Strain Improvement for Native and Heterologous Enzyme Production

Wild isolates of fungi do not typically produce enzymes at levels and cost that meet industrial demands. They normally produce just enough for their own benefit and only when it is necessary. Therefore, strains improvement for enzyme production is required and is performed in industry to increase the production yield. Most of production hosts in industry have been genetically improved to increase production capacity.

Before the advent of targeted genetic engineering, genetic strain improvement was based on classical mutagenesis that used physical and chemical mutagens such as X-ray irradiation, UV irradiation, ethyl methane sulfonate and nitrosomethyl guanidine, diethylsulfate (Kun *et al.*, 2019). These mutagens act directly on the genome of the microorganism, causing damage to the DNA, and resulting in mutations. Mutants are screened to identify those displaying higher enzyme activity, indicating higher level of enzyme production. Although the results of random genetic improvement are unpredictable, success has been realized in the past using these approaches and they are still in use. An example of successful strain improvement using X-ray mutagenesis was performed in *P. chrysogenum*, to increase the production of penicillin (Salo *et al.*, 2015). In addition, random mutagenesis has been used to improve fungal enzyme production, such as for glucose oxidase (Dubey *et al.*, 2017), alpha-amylase (Aleem *et al.*, 2018), and lipase (Bassegoda *et al.*, 2012). Parasexual segregation in *A. niger* has also demonstrated to be a suitable method as exemplified by improved chymosin production (Bodie *et al.*, 1994).

Until recently, the use of molecular genetics and gene transformation tools for production of recombinant heterologous enzymes was laborious due to the lack of genomic data and genome-editing tools. Currently the ability to introduce or delete genes becomes faster with the implementation of CRISPR/Cas9 technology (Ishino *et al.*, 2018).

Heterologous protein production in fungi may often undergo extensive modifications in the secretory pathway, including proteolytic processing and glycosylation, which could reduce the production yield. Different strategies have been developed to increase the production yield of heterologous proteins that include the construction of protease-deficient strains (Liu *et al.*, 2013; van den Hombergh *et al.*, 1995), improved secretion signals (van den Hombergh *et al.*, 1995; Gouka *et al.*, 1997; Moralejo *et al.*, 1999), use of strong promoters (Moralejo *et al.*, 1999), and integration of multiples copies of the foreign DNA, among others (Nevalainen and Peterson, 2014). Studies have been conducted on glycosylation in filamentous fungi and the main mode of glycosylation is by high mannose-type of sugars addition (Deshpande *et al.*, 2008). However, further development in this field is necessary to understand the bottlenecks in heterologous protein secretion.

Fungal protein secretion is linked to the physiology of the fungus. It has been established that the majority of native and heterologous proteins are secreted at the hyphal tip. An example is the production of a heterologous barley cysteine proteinase, which showed that secretion occurs solely at the hyphal tip in *T. reesei* (Nykänen *et al.*, 1997), supporting the hypothesis that modified strains with short filaments would improve protein secretion. In some cases, however, heterologous proteins such as *Hormoconis resinae* glucoamylase P and calf chymosin are secreted from mature parts of the hyphae in *T. reesei* (Inokuma *et al.*, 1988; Joutsjoki *et al.*, 1993a,b), implying that heterologous protein secretion and localization are protein dependent.

Enzyme Discovery

The growing world population, the diminishing fossil reserves and environmental concerns have increased the demand of biobased products and technologies. For example, the demand for biofuel is expanding to reduce greenhouse gas emissions (Khanna *et al.*, 2011). Enzymes are playing a major role in sustainable, biobased technologies. For the bioeconomy to thrive, new enzyme functionalities and more efficient enzymes are required to displace chemical processes. Enzyme discovery and enzyme engineering are two approaches pursued by industry to expand the functionality of enzymes to overcome the current shortcomings.

Genome Mining and Functional Metagenomics

(1) Genome mining

Nucleic acid and protein databases are rich resources for discovering novel enzymes (Aharoni, 2009). To date, around 300,000 genome sequences are available in the publicly accessible databases and about 180 million protein sequences available in the UniProt database. A systematic exploration of the available genome and protein resources with relevant bioinformatic tools can help to identify proteins of interest. For example, a known enzyme can be selected from a curated database and used as starting point to search for new enzymes performing the same or similar reactions in protein databases. The gene sequences encoding the selected enzymes with predicted activities can be retrieved and used as templates to clone or synthesize the genes of interest. The cloned or synthesized genes can be introduced by gene transformation methods into desired organisms for enzyme production and characterization. Characterized enzymes can be found in curated databases that include the Carbohydrate-active enZymes (CAZy) database (Lombard *et al.*, 2014), MycoCLAP (Strasser *et al.*, 2015) and the lipase engineering database (Fischer and Pleiss, 2003).

(2) Functional metagenomics

Massively parallel sequencing technologies, along with development of bioinformatic tools, are becoming a rapid strategy to discover enzymes in metagenomes (Kaul and Asano, 2012). Functional metagenomics starts from extracting DNA directly from a mixed population of organisms from diverse environments. A metagenomic library constructed with the extracted DNA is then screened for the production of enzymes (Steele *et al.*, 2009). For example, more than 100 new nitrilase genes

have been discovered from diverse geographical locations such as deep ocean beds, volcanic vents, and arctic tundra by metagenomics, allowing a creation of a library of enzymes for the conversion of nitriles to carboxylic acid (Desantis *et al.*, 2002). In addition, the DNA obtained from metagenomic studies can be sequenced and potential genes that code for catalytic enzymes can be searched based on sequence similarity or protein motifs using InterProScan (Jones *et al.*, 2014).

Functional metagenomics has been useful in discovering novel cellulases in a wide variety of natural thermophilic environments, such as continental geothermal pools and hot springs (Graham *et al.*, 2011), compost (McAndrew *et al.*, 2013) and hydrothermal vents (Placido *et al.*, 2015). Thermophilic enzymes have potential for industrial applications and their discovery by metagenomics has potential impact due to the difficulty of growing thermophiles or extremophiles microorganisms in the laboratory. However, a main limiting factor for the discovery of enzymes, especially from fungal origin, by functional metagenomics is that the host organism used for the metagenomic libraries is typically a bacterium (e.g. *E. coli*), in which the success rate of functional expression of eukaryotic gene low (Duan and Feng, 2010). In addition to metagenomics, metatranscriptomics, metaproteomics and high throughput screening have shown potential for enzymes discovery. For further understanding of the method of metatranscriptomics and metaproteomics for enzymes discovery, the reader is referred to (Warnecke and Hess, 2009) and (Kleiner, 2019).

Protein Engineering Approaches

Protein engineering of a specific enzyme (e.g., cellulase or hemicellulase) is an effective approach to enhance the enzyme activity, specificity and stability to suit diverse applications. This approach involves the engineering of modified catalysts to achieve desired functions. Directed evolution and rational enzyme design are two methods often used in protein engineering (Rigoldi *et al.*, 2018).

- **Directed evolution**

Directed evolution of enzymes consists of creating random mutations in the native enzyme. It can be performed by error prone mutagenesis (Yang *et al.*, 2017; Entzminger *et al.*, 2015), site-directed mutagenesis (Belsare *et al.*, 2017) or DNA shuffling (Lehtonen *et al.*, 2016). Directed evolution generates a library of enzyme variants. Activity screening of the library allows for the identification of enzymes with improved property. For example, directed evolution has been used to improve activity and stability of endo-beta-1,4-xylanase of *Thermomyces lanuginosus* by error prone PCR mutagenesis (Stephens *et al.*, 2007).

- **Rational design**

Rational design implies the use of computational design and modeling programs to improve the catalytic domain, the stability or additional properties of the enzymes *in silico*. It includes phylogenetic analysis and structural comparison to heterologous enzymes, which guide the rational design (Luke *et al.*, 2007). Among rational design strategies to improve enzyme stability, the introduction of disulfide bridges and/or surface hydrogen bonds are commonly used. Disulfide bridges and surface hydrogen bonds increase protein rigidity by locking their fold in the global conformation and by increasing protein rigidity respectively (Dombkowski *et al.*, 2014). Another strategy for rational enzyme engineering involves strengthening the well-packed hydrophobic cores which are involved in preserving enzyme stability and conformational specificity (Rigoldi *et al.*, 2018). Different computational tools have been developed to assist design and engineering of enzymes; for example, Rosetta (Zanghellini *et al.*, 2006), Orbit (Dahiyat and Mayo, 1996), Metal search (Desjarlais and Clarke, 1998) and Dezymer (Hellinga and Richards, 1991). Rosetta has been used to stabilize the local interactions of surface cavities of xylanases which resulted in 15 times increase in enzyme half life at 50°C compared to the native xylanases (Joo *et al.*, 2010). Increasing disulfide bridges by rational design has improved the thermostability of lipases in *Rhizopus chinensis* (Yu *et al.*, 2012). The rational design of enzymes suffers from drawbacks such as the unavailability of knowledge of proteins structure or the failure to prevent large hydrophobic clusters on the proteins surface (Tiwari *et al.*, 2012). Novel algorithms or methods to improve rational design are in continuous development.

Conclusion

Fungal enzymes have long played an important role in food and beverage production. They are now part of many industrial sectors, including detergents, textile, feed, pharmaceuticals and chemicals. Challenges remain in using fungal enzymes in industry; for example, low yields in the production of heterologous proteins, and cost of production of functionally diverse enzymes. Continuously improving fermentation processes and developing effective expression systems for native and heterologous fungal enzyme production will be key factors in expanding the use of enzymes in replacing chemical processes to enhance industrial sustainability.

Fungal Laccases as Biocatalysts for Wide Range Applications

Felipe de Salas and Susana Camarero, Spanish National Research Council, Madrid, Spain

General Aspects of Laccases

Laccases are phenol oxidases (EC 1.10.3.2) belonging to the multicopper oxidases (MCO) superfamily. Discovered in 1883 in the exudates of the lacquer tree *Toxicodendron vernicifluum* (Yoshida, 1883), laccases have been isolated from plants, fungi (ascomycetes, basidiomycetes and deuteromycetes), prokaryotes and arthropods, where they are involved in different biological processes. Fungal laccases are implicated in intra- and extracellular physiological processes including morphogenesis, pigmentation, pathogenesis, delignification and detoxification (Claus, 2004; Hoegger *et al.*, 2006; Morozova *et al.*, 2007). White-rot basidiomycetes responsible for wood decay in nature are among the main laccase producers together with the litter-decomposing fungi. They secrete laccases as part of an array of oxidoreductases, with ligninolytic peroxidases as the main players, enabling the efficient biodegradation of the lignin polymer (Eggert *et al.*, 1996; Lundell *et al.*, 2010).

Fungal laccases are mainly monomeric extracellular proteins although some basidiomycete (e.g., *Pleurotus ribis*, *Pleurotus pulmonarius*, *Trametes villosa*, *Cantharellus cibarius*) or ascomycete laccases (*Rhizoctonia solani*) consist of homodimers with each subunit with M_w similar to monomeric laccases (Morozova *et al.*, 2007). Laccases typically fold in three cupredoxin-like domains, each of them with a typical β -barrel topology. The protein structure is stabilized by two disulfide bonds, one located between domains one (D1) and three (D3), and the other between domains one (D1) and two (D2) (Fig. 1; Rivera-Hoyos *et al.*, 2013; Hakulinen and Rouvinen, 2015).

Laccases present four copper ions in the active site that act as cofactors for their catalytic activity. Depending on their UV/visible and electron paramagnetic resonance (EPR) spectroscopy properties, these copper ions are classified as follows: Type 1 (T1) copper, EPR detectable and with a strong absorption at 600 nm, is responsible of the blue color of laccases; Type 2 (T2) copper, colorless but detectable by EPR; and a pair of type 3 (T3) copper ions, with no EPR signal due to an antiferromagnetic coupling mediated by a bridging hydroxyl ligand, and weak absorbance at 330 nm (Jones and Solomon, 2015). The T2 and T3 coppers form the tri-nuclear cluster (TNC) where O_2 is reduced to water by the four electrons taken from four molecules of substrate at the T1 site (Sekretaryova *et al.*, 2019). T1 site is located in the D3 of the protein, while the tri-nuclear cluster (T2/T3) is embed between D1 and D3, with both domains providing residues for the coordination of the three coppers (arranged in a regular triangle). The T1 copper is coordinated by one Cys and two His. In the TNC, each of the T3 coppers have three His ligands and both are connected by an OH bridge, while the T2 copper is coordinated by two His (Jones and Solomon, 2015). The highly conserved Cys-His superexchange pathway (around 13 Å) serves as via to transfer the electrons from T1 site to the TNC (Fig. 2; Piontek *et al.*, 2002; Jones and Solomon, 2015). A conserved Asp residue (Asp 206 according to PM1 numbering) assists with His ligand (His455 according to PM1 laccase numbering) to the concerted electro-proton transfer at the T1 site (Galli *et al.*, 2013). Besides, there are two conserved acid residues (Asp 77 and Asp 453 according to PM1 laccase numbering) located close to the TNC that have a crucial role in O_2 reduction by aiding O_2 binding and providing protons (favored at acid pH) (Jones and Solomon, 2015).

According to the reduction potential of the T1 site, laccases can be classified as low (LRPLs, $E^0 < +500$ mV, most plant and prokaryotic laccases), medium (MRPLs, $E^0 +500$ to around $+700$ mV) and high (HRPLs, E^0 from $+720$ to $+800$ mV) redox potential laccases (Pardo and Camarero, 2015a). The latter are mainly produced by the white-rot, and litter-decomposing basidiomycete fungi and are of great biotechnological interest due to their high oxidation versatility (Hoegger *et al.*, 2006). These dramatic changes in laccase's redox potential are attributed to a perturbation in the geometry of the T1 site (Augustine *et al.*, 2008) that is in part modulated by the presence of a Met as the axial ligand in plant and bacterial laccases. The distorted tetrahedral geometry of the latter enzymes is replaced by a trigonal planar geometry in fungal laccases (MRPLs and HRPLs) with a non-coordinating residue (Leu or Phe) in the axial position (Hakulinen *et al.*, 2002; Piontek *et al.*, 2002). The influence of the axial amino acid in T1 redox potential has been demonstrated in several studies (Hall *et al.*, 1999; Xu, 2002). For instance, substitution of the axial ligand Met 502 in CotA laccase from *Bacillus subtilis* ($E^0 = 455$ mV) by non-coordinating Leu or Phe increases E^0 to 515 or 548 mV, respectively (Durão *et al.*, 2006).

Eukaryotic laccases show molecular masses between 60 and 130 kDa of which 10–50% may be attributed to glycosylation, mainly N-glycosylation (Xu *et al.*, 2019). N-glycosylation takes place in the lumen of the endoplasmic reticulum and is finalized in the Golgi (Burda and Aebi, 1999; Herscovics, 1999), and might influence secretion, proteolytic susceptibility, catalytic activity or thermal stability of laccases (Madhavi and Lele, 2009).

Laccases are capable to oxidize a wide range of different compounds, preferably *o*- and *p*-substituted phenols and aromatic amines, together with N-heterocycles (indole, benzothiazol, tetrahydroquinoline, hydroxyphthalimide, naphthol, etc), heterocyclic thiols, as well as some metals and organometallic complexes. The oxidation of these compounds only requires O_2 from the air as electron acceptor and produces water as sole-by product (Gianfreda *et al.*, 1999; Polak and Jarosz-Wilkolazka, 2012; Mogharabi and Faramarzi, 2014). The promiscuous activity and low catalytic requirements turn laccases into biocatalysts of choice for many different applications.

Fig. 1 Cartoon representation of the crystal structure of *Pycnoporus cinnabarinus* laccase (PDB 2XYB), showing the three cupredoxin domain (D1-D3) folding, the four catalytic coppers as spheres, and the two disulfide bridges in yellow. TNC refers to tri-nuclear cluster where oxygen is reduced to water and T1 Cu is the copper responsible for substrate oxidation.

Fig. 2 Catalytic site and catalytic mechanism of laccase. His (blue) and Cys (wheat) residues coordinating the catalytic coppers and conserved Asp residues involved in proton transfer (purple) are shown. The four coppers are depicted as spheres. Residues coordinating the four catalytic coppers and electron transfer from T1 site to the tri-nuclear cluster through the triplet H-C-H are shown based on PM1 laccase structure (PDB: 5ANH).

Catalytic Site and Reaction Mechanism of Laccases

The catalytic cycle starts with the oxidation of the substrate at the T1 site. It is assumed that laccase acts as a battery, storing the electrons from four monovalent oxidation reactions, which are transferred from the T1 site to the TNC to reduce one O_2 molecule to two H_2O molecules (Jones and Solomon, 2015). Consequently, the enzyme is transformed from the resting oxidized state into

Fig. 3 Redox mechanism of the high redox potential laccase from *T. versicolor* (TvL) vs the low redox potential laccase from *Rhus vernicifera* (RvL). Adapted with permission from Sekretaryova, A., Jones, S.M., Solomon, E.I., 2019. O₂ Reduction to water by high potential multicopper oxidases: Contributions of the T1 copper site potential and the local environment of the trinuclear copper cluster. *J. Am. Chem. Soc.* 141, 11304–11314. doi:10.1021/jacs.9b05230, American Chemical Society.

the fully reduced state (Fig. 3). Then, the interaction of the TNC with O₂ proceeds in two consecutive steps. In the first one, two electrons, one from the T2 Cu and the other from one of the T3 Cu ions of the fully reduced enzyme are donated to the molecular O₂ generating the peroxy intermediate. In the second step, the bond O–O is broken with the donation of two more electrons from the T1 and T3 copper sites, rendering the fully oxidized native intermediate (NI) of the laccase. A proton transfer, required for the reduction of molecular O₂ to water in the TNC, takes place at the same time as the electron transfer. The total reduction of NI by the oxidation of a new set of substrate molecules and the release of two water molecules will start a new catalytic cycle or, in case of lack of more substrate, the slow decay to the resting oxidized form will take place (Yoon and Solomon, 2007; Jones and Solomon, 2015).

Laccase Mediator Systems

The oxidation capabilities of laccase can be enhanced in the presence of low molecular weight compounds that act as redox mediators once oxidized by the enzyme. In the so-called laccase mediator systems (LMS), the oxidized mediator (“stabilized radical”) acts as a diffusible carrier, overcoming steric hindrances, to enable the oxidation of bulky substrates such as lignin, cellulose or starch polymers inaccessible to the enzyme, or of substrates with higher redox potentials that are not oxidized by the enzyme alone (Baiocco *et al.*, 2003; Camarero *et al.*, 2004; Kunamneni *et al.*, 2008; Cañas and Camarero, 2010). The 2,2′-azinobis (3-ethylbenzothiazoline-6-sulfonic acid) (ABTS), was the first compound described in the 1990s as laccase redox mediator for the enzymatic oxidation of non-phenolic lignin model compounds and the delignification and bleaching of paper pulps (Bourbonnais and Paice, 1990, 1992). Since then, the ability of other synthetic compounds such as 1-hydroxybenzotriazole (HBT), violuric acid, or 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO) to act as redox mediators of laccases has been demonstrated in a range of oxidation reactions of target compounds (Call and Mücke, 1997; Galli and Gentili, 2004; Xu *et al.*, 2009; Benzina *et al.*, 2012; Rostami *et al.*, 2018). Due to the different oxidation mechanisms, the use of different mediators may lead to different products (Baiocco *et al.*, 2003). Ultimately, the use of mediators adds higher versatility to the enzyme as biocatalyst.

The industrial application of LMS has, however, two main obstacles: the elevated cost of synthetic mediators and the possible generation and discharge in the industrial effluents of toxic intermediates. Substitution of synthetic mediators by low-cost natural mediators obtained from renewable sources constitute an efficient, eco-friendly and sustainable alternative for the application of LMS in white biotechnology processes. This is the case of certain phenolic compounds derived from lignin polymer that can be obtained as bio-products from the same industrial processes of biomass conversion in which laccases could be implemented (e.g., wood pulping and pulp bleaching). These natural phenolic compounds have been successfully assayed as laccases mediators in dye decolorization, detoxification of aromatic pollutants, pitch removal, delignification and bleaching of paper pulps or to enhance saccharification in biofuel production (Camarero *et al.*, 2005, 2007, 2008; Cañas *et al.*, 2007; Gutiérrez *et al.*, 2007; Kunamneni *et al.*, 2008; Cañas and Camarero, 2010; Babot *et al.*, 2011; Hollmann and Arends, 2012; Rico *et al.*, 2014; Pardo and Camarero, 2015b).

Heterologous Expression of Fungal Laccases

Enzyme overexpression is mandatory for its commercialization as industrial biocatalyst, and constitutes a challenging task in the case of basidiomycete laccases. Examples of overproduction of wild basidiomycete laccases are barely found in the literature. One outstanding example is the gram-scale production (1.5 g l^{-1}) of *P. cinnabarinus* wild type laccase by the monokaryotic *Pyconoporus cinnabarinus* ss3 strain using ethanol as inducer (Lomascolo *et al.*, 2003). The homologous overproduction of the recombinant native laccase was later achieved (1.2 g l^{-1}) by transforming a laccase-deficient *P. cinnabarinus* monokaryotic strain with the *P. cinnabarinus* laccase gene under the control of *Schizophyllum commune* glyceraldehyde-3-phosphate dehydrogenase (GAPDH) promoter (Alves *et al.*, 2004). The homologous overexpression of laccase III from *Coriolus (Trametes) versicolor* under control of the GAPDH promoter was also reported, although no enzyme yields were informed (Kajita *et al.*, 2004). Homologous expression of *Coprinus cinerea* *lcc1* under the control of various homologous and heterologous promoters was proved as well, obtaining also the highest laccase activity (3 U ml^{-1} with ABTS) with the promoter of GAPDH from *Agaricus bisporus* (Kilaru *et al.*, 2006).

The difficult genetic manipulation of the natural producer strains, together with the lack of GRAS (generally recognized as safe) status and optimized scale-up protocols for industrial fermentation of wild laccases, discouraged the use of basidiomycete strains to engineer and produce laccases so far, drawing the attention to heterologous expression hosts (Otterbein *et al.*, 2000). To this end, optimization of laccase CDS according to the codon usage of the heterologous host, selection of adequate expression vectors and signal peptides and optimization of the expression conditions are carried out with dissimilar results.

The bacterium *Escherichia coli* is successfully used for the expression, engineering and scale up production of bacterial laccases (Alessandra *et al.*, 2010; Hämäläinen *et al.*, 2018), but the effective expression of active fungal laccases in bacteria has not been achieved so far, most likely due to differences in their post-translational processing machineries (Salony *et al.*, 2008; Ma *et al.*, 2018).

By contrast, ascomycete expression systems (both yeasts and filamentous fungi), well established for the industrial production of eukaryotic enzymes, are well suited as heterologous hosts for the functional expression of basidiomycete laccases. However, the levels of basidiomycete enzymes produced in these systems are often much lower than those of ascomycete enzymes. Some of the reasons behind this fact may be: (1) the disparities in basidiomycete and ascomycete gene models (basidiomycete genes often have more introns with less conserved start and stop sequences), (2) the sensitivity of basidiomycete laccases to ascomycete proteases (3) the induction of the repression under secretion stress (RESS) mechanism which downregulates the transcription of genes encoding secreted proteins or (4) the activation of mRNA-destabilizing proteins which may affect the heterologous mRNA stability, thereby diminishing the production of heterologous proteins (Su *et al.*, 2012; Casado López *et al.*, 2016).

The low expression yields and frequent hyperglycosylation of recombinant proteins hinder the use of the yeast *Saccharomyces cerevisiae* as industrial host (Herscovics, 1999), whereas the powerful methanol-inducible alcohol oxidase (AOX1) promoter and the high-density growth of the yeast *Pichia pastoris* (up to $\text{OD}_{600} = 500$ in bioreactor) provide, in general, higher enzyme yields. Conversely, variable enzyme expression yields are obtained depending on the characteristics of the heterologous protein, which makes this expression system weakly predictable (Cereghino, 2002; Mate *et al.*, 2013; Wang *et al.*, 2016). The highest enzyme yields ever reported (550 mg l^{-1}) for a basidiomycete laccase produced in *P. pastoris* in fed-batch fermentation corresponds to *T. versicolor* laccase using AOX1 promoter (Hong *et al.*, 2002). Constitutive promoters such as the GAPDH have also been assayed. That is the case of fed-batch fermentation of *P. pastoris* producing POXA1b laccase from the basidiomycete *Pleurotus ostreatus*, where constitutive production under GAPDH outperformed the enzyme levels obtained in AOX-induced cultures (Pezzella *et al.*, 2017). This is in agreement with results obtained with the ascomycete *Botrytis aclada* laccase (Kittl *et al.*, 2012), where the enzyme levels were about $40\text{--}60 \text{ mg l}^{-1}$.

Replacement of the native laccase signal peptide by the *S. cerevisiae* α -factor signal sequence is frequently applied to increase the production of the recombinant enzyme by yeast. This approach was successfully used to express, for instance, two laccases from the white-rot fungus *Physiporus rivulosus* in *P. pastoris* (Hildén *et al.*, 2013). Moreover, the directed evolution of the laccase encoding sequence fused to the α -factor pre proleader was successfully used in several enzyme engineering works to increase the secretion of fungal laccases by *S. cerevisiae* (Bulter *et al.*, 2003; Mate *et al.*, 2010; Camarero *et al.*, 2012; Pardo *et al.*, 2012). This strategy has recently rendered outstanding laccase production yields in *S. cerevisiae* (25 mg l^{-1}) in our laboratory (de Salas *et al.*, 2019a).

Among all the host systems used for protein expression, filamentous fungi show the highest expression levels especially when the secreted protein is homologous or is from fungal origin. Even if the genetic manipulation of filamentous fungi is more complex than that of yeasts, the high expression yields of active enzyme and the low cost of the growth media (filamentous fungi show enormous nutrition flexibility) make them the preferred hosts for production of industrial enzymes (Fig. 4). There are several examples of basidiomycete laccases heterologously expressed in *Aspergillus*, *Trichoderma* or *Penicillium* (Abianova *et al.*, 2010). The highest expression yields (close to gram per liter) have been reported in *Aspergillus* (Couto and Toca-Herrera, 2007; Alessandra *et al.*, 2010). For instance, gram-scale production of a laccase from *Trametes* sp. C30 has been achieved in *A. niger* (Mekmouche *et al.*, 2014). The heterologous production of other native basidiomycete laccases and their variants engineered *in vitro* has also been attained in this species although at a lower scale, i.e., *P. cinnabarinus* wild-type laccase (145 mg l^{-1} , Record *et al.*, 2002) and an *in vitro* evolved variant (23 mg l^{-1} , Camarero *et al.*, 2012), and wild-type POXA1b and its 1H6C variant (13 mg l^{-1} and 20 mg l^{-1} , respectively, Macellaro *et al.*, 2014). *Aspergillus oryzae* is the preferred host for producing industrial enzymes at Novozymes (world leader company in commercializing industrial enzymes), such as the high-redox potential laccase from *T. villosa* commercialized as NS 51002 (no longer available) and the ascomycete *Myceliophthora thermophila* laccase (NS 51003). This expression system has been used for the overexpression of basidiomycete laccase variants developed in our lab by directed evolution to an industrial relevant scale in Novozymes (de Salas *et al.*, 2016, 2019b).

Fig. 4 Comparison of yeast and filamentous ascomycetes as heterologous hosts for laccase production.

Fig. 5 Some examples of laccase applications.

Enzymes can substitute chemical catalysts in diverse reactions providing the advantages of less toxicity than chemical catalyzers and increasing the selectivity in some cases. Nevertheless, the frequent demanding conditions of the industrial processes (extreme pH, high temperature, presence of co-solvents or inhibitors, etc.), together with the recalcitrance of some substrates or selectivity requirements are main hurdles for the application of wild-type enzymes in industrial processes. Therefore, the engineering of the enzyme is often required to adjust the activity and stability of the enzyme to the operating conditions or to design new or improved activity or selectivity towards specific substrates. Although this step, together with the aforementioned overexpression of the enzyme, is indispensable to apply laccases at industrial scale, this is not within the objectives of this chapter, and there are other reviews dealing with this subject (Kunamneni *et al.*, 2008; Gonzalez-Perez *et al.*, 2012; Pardo and Camarero, 2015b).

Biotechnological Applications

Laccases, alone or in LMS, are multipurpose biocatalysts with application in a wide range of industrial processes (Fig. 5).

Fungal laccases are commercialized as industrial enzymes by Novozymes (Denmark), Jena Biosciences (Germany), Creative Enzymes (USA), Ecostar (India), USBiological (USA), ASA Spezialenzyme (Germany), etc. Bacterial laccases are produced and

commercialized by MetGen (Finland). So far, there are quite a few successful cases of laccases formulated and commercialized for target-applications: Denim fabric finishing (DeniLite®), paper pulp delignification and bleaching (Novozyme NS-51003, MetZyme® LIGNO™), O₂ depletion to preserve flavors from food and beverages (Flavourstar®) or treatment of wine cork stoppers (Suberzyme®). Nevertheless, there is room for the application of laccases in other industrial sectors, as demonstrated in many research studies commented below.

Pulp and Paper Industry

Due to the natural activity of laccases on phenolic lignin, one of the first applications of laccases studied was precisely related to the delignification of wood pulp in the pulp and paper industry (Bourbonnais and Paice, 1992). Laccase-mediator systems can be applied for pulp bleaching and delignification to remove the residual lignin remaining in the paper pulp after cooking. The integration of a laccase-based enzymatic stage in the totally chlorine-free (TCF) or elemental chlorine-free (ECF) bleaching sequences can improve the brightness of the pulp, reduce the use of chlorine-based harsh chemicals in ECF bleaching and, simultaneously, enhance pulp strength properties while reducing the energy consumption during refining of the pulp (García *et al.*, 2003; Camarero *et al.*, 2004; Ibarra *et al.*, 2006). Other applications of laccases related with the paper industry are: (1) fiber functionalization through oxidative coupling of low molecular weight compounds (such as phenols) to the paper surface, which enhances paper strength and resistance to water absorption or adds new properties such as antioxidant activity; (2) removal of lipophilic extractives deposited in the bleached pulps ("pitch control"); (3) deinking of secondary fibers; or (4) enzymatic treatment of the effluents from paper mills (Gutiérrez *et al.*, 2007; Widsten and Kandelbauer, 2008; Madhavi and Lele, 2009; Garcia-Ubasart *et al.*, 2011; Fillat *et al.*, 2012; Cusola *et al.*, 2015). Recent functionalization examples by LMS include the grafting of carboxymethyl cellulose and chitosan on kraft pulp fibers to obtain high-resistance papers (Ballinas-Casarrubias *et al.*, 2017) or functionalization of bacterial cellulose to produce paper-silver nanoparticles composites with antimicrobial activities (Morena *et al.*, 2019).

Textile Industry

Laccases can improve the dyeing efficiency and reduce the cost of the dyeing process by *in situ* oxidation of inexpensive precursors after their adsorption by the fabric, and aid textile bleaching by avoiding back staining by degrading the released dyestuff after dyeing or by bleaching the textile fibers from natural dyes or impurities (Vasil'eva *et al.*, 2008). Some of the first developed commercial laccase formulations are used for denim fabric finishing (fading of indigo-dyed denim) to give the characteristic gray cast (Galante and Formantici, 2003; Pezzella *et al.*, 2015). Laccases have also been used for functional modification of molecules on textile fabrics such as cotton or wool, improving properties as water repellence or resistance (Lantto *et al.*, 2004; Guimarães *et al.*, 2011; Pezzella *et al.*, 2015). *In situ* polymerization of catechol and *p*-phenylenediamine catalyzed by laccase on different fabrics can yield colored low-conductive fabrics with good fastness behavior after washing (Su *et al.*, 2019a). Moreover, this polymerization reaction has been used for coating wood, cotton and polyethylene terephthalate fabrics to provide antimicrobial properties against gram-positive and gram-negative bacteria. These enzyme-treated textile fabrics are of special interest in hospitals to reduce the spread of nosocomial diseases (Su *et al.*, 2019b).

Waste Treatment

More demanding environmental regulations have pushed laccases to new application opportunities in waste treatment and disposal (Pezzella *et al.*, 2015). Laccase can transform toxic recalcitrant compounds into less toxic and more degradable derivatives by direct dechlorinating, cleavage of aromatic rings or oxidative transformation of heterocycles and polycyclic aromatic hydrocarbons in hydroxylated intermediates (Schultz *et al.*, 2001; Cañas *et al.*, 2007; Teng *et al.*, 2019). Wastewaters from the food, textile, dye or printing industries enriched in phenols and aromatic amines can be detoxified with laccases (Lante *et al.*, 2000; Madhavi and Lele, 2009). For example, a mix of fungal enzymes containing laccases applied to winery-derived biomass (in combination with a sonication pretreatment) shortened the degradation time required with fungal degradation and produced commercially useful compounds such as gallic acid, lactic acid and glycolic acid (Karpe *et al.*, 2017). The removal of emergent organic pollutants catalyzed by laccase has also been described. For instance, deamination and demethylation of tetracycline and oxytetracycline antibiotics was recently attained with a fungal laccase (Tian *et al.*, 2020).

Synthetic organic dyes are very stable to temperature, light and microbial attack, making them difficult to degrade. The world total dye production per year is around 800,000 tons, of which at least 10% is released to the environment through wastewaters where they are a source of eutrophication and can form toxic by-products through oxidation, hydrolysis or other chemical reactions (Konstantinou and Albanis, 2004). Traditional methods for color removal from these wastewaters, such as filtration, adsorption or coagulation-flocculation, are expensive and have operational problems. Laccases can catalyze the decolorization of a wide range of synthetic organic dyes alone or in the presence of redox mediator compounds (Claus *et al.*, 2002; Gubitz *et al.*, 2002; Camarero *et al.*, 2005). The decolorization is most frequently linked to detoxification. Detoxification of phenolic azo dyes by laccase was proved by the asymmetrical breakdown of the azo linkage releasing molecular nitrogen, avoiding aromatic amine formation (Chivukula and Renganathan, 1995). Other example of azo dye degradation is the use of a laccase from *T. versicolor* for the degradation of orange 2 and acid orange 6 which degradation products were non-toxic (Legerská *et al.*, 2018).

Food and Beverages

One relevant example of laccase's application in food and beverage processing is found in the wine industry to substitute the use of SO₂ for the removal of phenolic compounds involved in the maderization of wine, a process that causes turbidity, color intensification, and aroma and flavor alterations. The polyphenols are oxidized by the enzyme, polymerized and removed by clarification. Similar uses have been proposed for the treatment of fruit juices and beer. "Flavourstar" commercial laccase manufactured by Novozymes A/S is used to remove oxygen from finished beer in order to avoid its reaction with proteins or fatty acids, which prevents the formation of off-flavor compounds (Osma *et al.*, 2010). A process that uses laccase as dough additive in baking has also been patented. This process increases the volume and softness of the baked product and at the same time increases strength, stability and reduces the stickiness of the dough, thereby improving its machinability. It has been suggested that this effect is produced by the oxidizing effect of the laccase in the dough components improving the strength of the dough gluten structures (Minussi *et al.*, 2002; Pezzella *et al.*, 2015).

Biosensors

Some optical and thermal biosensors have been reported using laccases, although electrochemical biosensors where laccase is covalently immobilized in carbon-based electrodes, to allow a direct electron transfer, has been widely demonstrated for detection of phenols with low detection limit and high sensitivity (Li *et al.*, 2012; Rodríguez-Delgado *et al.*, 2015). The performance of the biosensor clearly depends on the enzyme immobilization strategy (Casero *et al.*, 2013). A recent study combined botryosphæran fungal biopolymer with multi-walled carbon nanotubes to immobilize laccase in the electrode, obtaining a novel biosensor for the determination of dopamine and spironolactone with good selectivity (Coelho *et al.*, 2019). As an example of how far the application of laccases in biosensors can go, a textile biosensor was constructed by functionalizing cotton yarn with a semiconducting polymer on which laccase was absorbed. It was demonstrated to monitor human health biomarkers (e.g., Tyr) in a non-invasive way, finding potential application in sport, healthcare and working safety (Battista *et al.*, 2017). Another example is the design of a pH responsive color-changing wool with conductive features through laccase-catalyzed polymerization of diaminobenzenesulfonic acid (Zhang *et al.*, 2018). In the last years, intensive research has been done on the application of laccases in enzymatic biofuel cells through their immobilization in nanocarbon cathodes modified with metal nanoparticles. This technology, with applications in biosensing, bioreactors or bioenergy conversion (Sekretaryova *et al.*, 2016; Zhang *et al.*, 2017; Rodríguez-Padrón *et al.*, 2018), offers higher redox potentials than commercial fuel cells, but it requires more development studies to be commercialized (Ghosh *et al.*, 2019).

Laccases in Organic Synthesis

The synthesis of chemical organic compounds catalyzed by laccase (with or without mediators) has attracted the attention of intensive research in the last two decades to provide a more efficient, cleaner and sustainable alternative to the use of expensive catalysts or toxic reagents.

Laccases can catalyze the synthesis of colorful organic compounds that can be used as dyes through the oxidation of various phenolic and aromatic precursors. Catechol or indole derivatives (Ganachaud *et al.*, 2008; Kim *et al.*, 2011), phenoxazine-derived dyes such as cinnabaric acid (Eggert *et al.*, 1995; Bruyneel *et al.*, 2008), and several azo dyes have been obtained with laccase as biocatalyst (Polak and Jarosz-Wilkolazka, 2012). The latter are the most used dyes in paper printing and textile dyeing, where they account for around 50% of the world total dye production due to their color variety (Konstantinou and Albanis, 2004). Some examples of azo dye synthesis by laccase include an azo dye with two anthraquinoinic sulfonated chromophores obtained with immobilized *Perenniporia ochroleuca* MUCCL 41114 laccase (Enaud *et al.*, 2010), or the homocoupling reaction of 4-methylamino benzoic acid mediated by laccase (Martorana *et al.*, 2011). The coupling of phenylenediamine and α -naphthol catalyzed by *P. ostreatus* POXA1b laccase renders SIC-RED dye, while the coupling of resorcinol and 2,5-diaminobenzenesulfonic acid renders other colored compounds (Pezzella *et al.*, 2016; Giacobelli *et al.*, 2018). The use of 1-naphthol and 1-naphthol-8-amino-3,6-disulfonic acid as precursors catalyzed by a fungal laccase engineered in our lab also rendered a new acidic dye with excellent dyeing properties (de Salas *et al.*, 2019a).

Laccases also catalyze the synthesis of pharmaceutical compounds of high value. Some examples are the enzymatic oxidation of 4-methyl-3-hydroxyanthranilic acid to obtain actinocin, a proven antitumoral compound (Osiadacz *et al.*, 1999; Burton, 2005), or the synthesis of the powerful antitumoral drug vinblastine by oxidative coupling of katarantine and vindoline (Sagui *et al.*, 2009). These enzymes have been used to conjugate catechins and dextran to obtain drugs with anticancer activities, or to obtain new derivatives from resveratrol and the hormone β -estradiol (Nicotra *et al.*, 2004a,b; Vittorio *et al.*, 2016). The regioselectivity of some LMS in oxidation reactions saves time and money compared with chemical organic synthesis. Fungal laccases and TEMPO as mediator can selectively oxidize the primary hydroxyl group in monosaccharides and disaccharides under mild conditions for their application in different technical areas (Marzorati *et al.*, 2005). A laccase from *Trametes pubescens* and TEMPO were used for the oxidation of the primary hydroxyl group of natural glycosides amygdalin or colchicoside to the corresponding carbonyl groups (Baratto *et al.*, 2006). Laccase-TEMPO can also selectively oxidize glycerol to generate glyceraldehyde and glyceric acid (Liebminger *et al.*, 2009), or enhance the antioxidant activity of propolis, attributed to the formation of hydroquinone, catechol and phloroglucinol (Botta *et al.*, 2017). More recently, it has been discovered that laccases are capable of selective phenol coupling, as a tailoring step of polyketide synthesis, in the absence of auxiliary proteins. Polyketides are a structurally and functionally diverse class of bioactive natural compounds proven to be a rich source of pharmaceutical and agrochemical lead compounds (Fürtges *et al.*, 2019).

Amination reactions catalyzed by laccase are of interest due to the antibacterial, antifungal, antiallergenic, anti-inflammatory and anticonvulsant activities of aniline derivatives (Niedermeyer *et al.*, 2005). For example, reaction of anilines with 2,5-dihydroxybenzoic acid derivatives catalyzed by laccase renders N-analogous of corollosporines with important antimicrobial activity (Mikolasch *et al.*, 2008). Other examples are the synthesis of 5-alkylaminobenzoquinone and 2,5-bis(alkylamino) – 1,4-benzoquinone by oxidative coupling of 2-methoxy-3-methylhydroquinone and primary amines, such as octylamine, cyclooctylamine, and geranylamine (Herter *et al.*, 2011); the dimerization of salicylic esters or bisphenol A (Ciecholewski *et al.*, 2005); the stereoselective amination of racemic sec-alcohols by laccase-TEMPO (Martínez-Montero *et al.*, 2017); and the synthesis of triaminated cyclohexa-2,4-dienones using catechol and primary amines as precursors (Wellington *et al.*, 2018). Laccases also catalyze the synthesis of cyclic products using 2,5-dihydroxybenzoic acid derivatives, and aromatic and heteroaromatic amines as precursors through oxidative C–N bond formation followed by cyclization (Hahn *et al.*, 2010). Another cyclization reaction catalyzed by laccases is the bioconversion of 2',3,4-trihydroxychalcone to 3',4'-dihydroxyaurone. Aurones are plant secondary metabolites with significant biological activity including anti-cancer, anti-parasitic and enzyme-inhibitory activity (Zerva *et al.*, 2019).

Oxidative coupling and polymerization reactions catalyzed by laccase

The oxidative coupling of phenols or aromatic amines is one of the most useful abilities of laccases that have been learned from nature, and which are widely exploited in organic synthesis reactions. Lignification of the plant cell walls consists of the oxidative coupling of phenolic precursors, the cinnamyl alcohols, catalyzed by plant laccases and peroxidases. The electronic delocalization enables the radicals to couple at *o*- and *p*-positions through different ether and aryl-alkyl linkages to yield diverse polymeric products (type of lignins) depending on the abundance of precursors available in the plant or tissue (Boerjan *et al.*, 2003). Accordingly, two different dimeric products (with C–O or C–C bonds) are obtained from *in vitro* oxidation of ferulic acid catalyzed by laccase, while *in vitro* oxidation of sinapic acid leads to a single C–C bonded dimer (Tranchimand *et al.*, 2006; Mogharabi and Faramarzi, 2014). The laccase-ABTS system has been used for the catalysis of the oxidative coupling of heterocyclic thiols, rendering their corresponding disulfides, which have numerous applications such as drug delivery systems, vulcanizing agents or as intermediates for the synthesis of sulfinyl and sulfenyl compounds (Abdel-Mohsen *et al.*, 2013).

While the enzymatic polymerization of syringic acid or DMP is regioselective, yielding chains of poly-phenylene oxide units (Ikeda *et al.*, 1996b, 1996a), other oxidative coupling reactions can lead to non-controllable polymer structures with undesirable characteristics. Different strategies have been developed for gaining control of the process and obtaining the desired polymer structure. The presence of organic co-solvents, such as 1,4-dioxane or methanol, increases the solubility of the aromatic substrates leading in some cases to an important control over the polydispersity and polymer size (Hollmann and Arends, 2012). In addition to classical organic solvents, ionic liquids have been used as co-solvents for polymerization of phenols (Sgalla *et al.*, 2007; Eker *et al.*, 2009; Khlopova *et al.*, 2016). These chemicals can increase substrate solubility or act as enzyme immobilization matrix, enabling enzyme recycling during the reaction. It has also been observed that ionic liquids stabilize the enzyme in the presence of anionic surfactants required for example for the synthesis of polyaniline, thus increasing polymer yields (Zhang *et al.*, 2014). Regioselectivity is crucial for most polymerization reactions and it can be achieved by substrate engineering. For example, linear conductive polyaniline can be obtained without templates by blocking the *o*-position of aniline. However, this strategy yields a less conductive and electroactive polymer than the standard chemical synthesis of polyaniline (Kim *et al.*, 2007). Some compounds can act as scaffold (templates) during the polymerization reaction to avoid branch formation. These templates are molecules with generally long chain structures that direct the proper alignment of the monomers. In some cases, they are negatively charged, what serves as counter ion (dopant) for the synthesized polymer (Hollmann and Arends, 2012). While templates are often used to achieve polymerization of phenolic precursors, polyaniline synthesis is one of the most significant examples of the use of templates to aid the synthesis of a linear polymer (Kim *et al.*, 2005).

Synthesis of polyaniline catalyzed by laccase

Chemical synthesis of conductive polyaniline is relatively cheap due to the low cost of aniline and the high product yields. However, this synthesis is far from being environmentally friendly due to the elevated quantities of toxic oxidants needed and the very acidic pH of the reaction, releasing large quantities of pollutants (Shumakovich *et al.*, 2011). Even more, the polyaniline (PANI) obtained from the chemical polymerization of aniline is soluble only in some organic solvents, making the processability of the product difficult and, hence, increasing the cost of its application (Huang and Kaner, 2006).

On the other hand, the enzymatic polymerization of aniline to produce conductive PANI is environmentally friendly, avoiding the use of chemical oxidizers and allowing to increase the pH of the reaction up to 3.5. The pH of the reaction must be kept below the pK_a of aniline – 4.6 at 25°C- to have a prevalence of anilinium cations in the reaction). Higher pH values implicate the prevalence of neutral aniline that yields PANI oligomers with low or none electroconductive capabilities (Sapurina and Stejskal, 2008). Also as aforementioned, only a linear polyaniline can display conductive capabilities. To obtain head to tail polymers and to avoid parasitic branch formation, a co-solvent or template must be present during the reaction (Ćirić-Marjanović *et al.*, 2017). Still some template-free synthesis studies of polyaniline using laccase as biocatalyst have been reported. Conductive cotton and bacterial cellulose have been obtained in a free template reaction by *in situ* polymerization of aniline by laccase using HBT as mediator in an ultrasonic bath (Su *et al.*, 2018; Shim *et al.*, 2019).

Fig. 6 Scheme of the synthesis of conductive PANI carried out in our lab using an engineered laccase and sodium dodecylbenzenesulfonate (SDBS) as template.

However, most often the template-free polymers are less defined and with an unclear protonation or oxidation states (Ćirić-Marjanović *et al.*, 2017).

Polyelectrolytes like anionic surfactants, poly(vinylphosphonic acid), sulfonated polystyrene or even DNA are commonly used as templates for the synthesis of electroactive PANI (Liu *et al.*, 1999; Nagarajan *et al.*, 2000, 2001; Karamyshev *et al.*, 2003). Among templates, anionic surfactants are preferred due their commercial availability and capability to maintain the water solubility of PANI, thus increasing its processability. These templates aggregate to form micelles over a critical micellar concentration, providing a suitable local environment for aniline *p*-coupling (Hino *et al.*, 2006). The polymerization process of aniline associated to this micellar structure yields water soluble PANI, that can be precipitated with ethanol or acetone that disaggregate the anionic surfactant micelles (Streltsov *et al.*, 2008). Different macromolecular structures can be obtained by changing the anionic surfactant during the enzymatic synthesis of PANI. Anionic surfactants usually inhibit enzyme activity by protein denaturation, although the presence of aniline protects the enzyme from the action of the surfactant (Otzen, 2011). The use of different anionic surfactants and different concentrations yields polyaniline with different spectrometric and macromolecular structures. Polyaniline with excellent electrochemical and electro-conductive properties was synthesized by using a fungal laccase variant engineered in our lab in the presence of sodium dodecylbenzenesulfonate (SDBS) as doping template (Fig. 6). The PANI obtained is displayed in nanofibers, which provides additional advantages over other macromolecular assemblies like a porous structure and a large surface-to-volume ratio, which are optimal properties for biosensor development (de Salas *et al.*, 2016). More recently, polyaniline's production yield has been enhanced up to 87% (w/w, referred to aniline precursor) by the additional engineering of the laccase through directed evolution and semi-rational design (de Salas *et al.*, 2019a).

Conclusions

The high redox potential of some fungal laccases boosts their capabilities to oxidize diverse aromatic compounds, which together with the use of O_2 from the air as sole catalytic requirement, make these enzymes biocatalysts of choice for many industrial sectors. Some of the first applications of fungal laccases were related to the pulp and paper industry, taking advantage of their intrinsic high activity on lignin phenols associated with their natural function in plants and fungi. Their use as biocatalyst in textile, food and beverage industries and waste treatment have also been historically targeted in many research studies. In the last two decades, new research studies emerged to open the range of laccase's applications to biosensor design or to catalyze organic synthesis reactions with promising results. Many of the examples described have been relegated over the years to the laboratory environment. The difficult overexpression of fungal laccases and need to adjust their catalytic activity and stability to specific operating conditions are main hurdles for the industrial application of these enzymes. However, new and more restrictive environmental regulations could be the catalyzer for the implementation of some of these new enzymatic processes to an industrial scale.

Plant Cell Wall Structure and Composition

Plant cell walls provide strength to the plant and are important for e.g., plant growth, cell differentiation, intercellular communication and water movement. They also protect plants from abiotic and biotic stresses including microbial attack (Cosgrove, 2005). Plant cell walls are mostly composed of polymeric compounds, the most abundant of which are the carbohydrates cellulose and hemicelluloses, and aromatic lignin. These polymers are arranged to a complex network that is called lignocellulose. In addition, the cell walls contain pectins, structural proteins and extractives, such as terpenes, resins and phenols. Plant cell walls have three different layers that are the primary and secondary walls, and the middle lamella, each of which have unique structure and chemical composition (Harris and Stone, 2009). Furthermore, the composition of the plant cell walls has significant differences between plant species and tissues as well as the growth phases of the plant (Eriksson *et al.*, 1990).

Lignin

The aromatic heteropolymer lignin is, after cellulose, the second most abundant biopolymer on earth. In the plant cell walls, lignin is cross-linked to hemicellulose and provides plant with strength, facilitates water transportation and protects the cell walls from microbial attack (Eriksson *et al.*, 1990; Harris and Stone, 2009). Lignin is synthesized in plant cell walls by enzymatic polymerization of phenylpropanoid monolignols, i.e., *p*-coumaryl, coniferyl and sinapyl alcohols, to *p*-hydroxyphenol, guaiacyl and syringyl subunits, respectively (Higuchi, 1990). These subunits are linked together with various C–C and ether bonds, of which the β -aryl-ether (β -O-4) linkage is the most abundant (Vanholme *et al.*, 2010). Mainly guaiacyl subunits are present in softwoods that contain 27%–32% lignin (as dry weight), while both guaiacyl and syringyl subunits exist in hardwoods where lignin forms 21%–31% (as dry weight) of the cell wall (Sjöström, 1993). Herbaceous plants contain all three lignin subunits and their lignin amount varies greatly, from 5% to 10% in grasses (Schaefer *et al.*, 1985; van Soest, 1982) up to 23% in crop straw (Buranov and Mazza, 2008). While being present in all plant cell wall layers, most of the lignin is in the thick secondary cell wall, but middle lamella has the highest lignin concentration. The heterogeneous, irregular structure of lignin with non-hydrolyzable interunit linkages makes its biological degradation difficult and also restricts obtaining complete knowledge of the chemical structure of native lignin molecules.

Plant Cell Wall Carbohydrates

Up to 40%–50% of plant dry weight is cellulose that is the most abundant polymer in plant cell walls and gives them rigidity. Cellulose is a linear homopolysaccharide of repeating D-glucose units that are joined together by β -1,4-linked glycosidic bonds (Sjöström, 1993). The linear cellulose chains are connected by intermolecular hydrogen bonds to microfibrils that contain highly organized crystalline regions and less organized amorphous regions (Ding and Himmel, 2009). Orientation of these rigid microfibrils differs between the secondary cell wall sublayers (Harris and Stone, 2009).

Hemicelluloses are branched heteropolysaccharides that are linked to cellulose microfibrils by hydrogen bonds, therefore supporting the cell wall structure (Harris and Stone, 2009). Approximately 20%–30% (as dry weight) of plant matter is hemicelluloses. Four main types of hemicelluloses are xylan, xyloglucan, β -glucan and mannan, and their backbones are built from β -1,4-linked D-xylose, β -1,4-linked D-glucose, β -1,3;1,4-linked D-glucose and β -1,4-linked mannose residues, respectively. These backbones are decorated with branched monomers and short oligomers that include D-galactose, D-xylose, L-arabinose, L-fucose, D-glucuronic acid, acetate, ferulic acid and *p*-coumaric acid (van den Brink and de Vries, 2011).

Pectins are the most complex hemicelluloses, which provide additional crosslinks between cellulose and hemicelluloses, and are mainly found in the primary cell wall and middle lamella. D-Galacturonic acid is the main monomer present in four different pectin substructures that are homogalacturonan (HGA), xylogalacturonan (XGA), rhamnogalacturonan I (RG-I) and rhamnogalacturonan II (RG-II) (Mohnen, 2008). HGA, XGA and RG-II have a linear backbone of α -1,4-linked D-galacturonic acid residues. In HGA, the backbone can be methylated and acetylated, whereas in XGA, the backbone is substituted by β -1,3-linked D-xylose residues. RG-II is a minor component of pectin and its D-galacturonic acid backbone can contain at least 12 different glycosyl residues. RG-I is the most complex pectin structure, which backbone consists of alternating D-galacturonic acid and L-rhamnose residues and have chains of L-arabinose and/or D-galactose linked to the L-rhamnose residues. In addition, RG-I can have branched polysaccharides such as arabinogalactan and arabinan as its side chains, which are often referred to as the “hairy” pectin regions. (Caffall and Mohnen, 2009).

In this chapter, we do not discuss about carbohydrate degrading enzymes of basidiomycete fungi, which have been extensively reviewed e.g., by Rytioja *et al.* (2014).

Lignin-Modifying Fungi

Lignin-modifying fungi are the only organisms capable of efficiently mineralizing lignin into CO₂ (Blanchette, 1995). They usually belong to the phylum Basidiomycota, but some ascomycete species can also modify lignin (e.g., Xylariales species) (Worrall *et al.*, 1997). The potential of mineralization of lignin is however lower in *Xylaria* spp. than in basidiomycete fungi (Liers *et al.*, 2011, 2006). Lignin-modifying species have been broadly divided into white-rot and brown-rot fungi according to the visual appearance they cause to wood residue during decay.

White-Rot Fungi

White-rot fungi (e.g., *Phanerochaete chrysosporium*, *Dichomitus squalens*, *Trametes versicolor*) are the most efficient lignin degraders in nature (Eriksson *et al.*, 1990). They are able to degrade all structural constituents of the plant cell wall including lignin. These fungi secrete lignin-modifying enzymes such as class II heme peroxidases, laccases and H₂O₂-producing enzymes to get access to plant polysaccharides, which they can use as carbon sources (Kirk and Farrell, 1987). White-rotted wood has a soft and bleached appearance with fiber-like cellulose-enriched material (Hatakka and Hammel, 2010). In addition, black spots of manganese dioxide deposits are typically observed in the wood colonized by white-rot fungi (Daniel and Bergman, 1997; Eriksson *et al.*, 1990). Although white-rot fungi are predominantly found in hardwood, also litter-decomposing fungal species (e.g., *Agrocybe praecox*, *Stropharia coronilla*) cause white-rot type decay.

Brown-Rot Fungi

Brown-rot fungi are most commonly found on conifer trees and they all belong to Basidiomycota (e.g., *Gloeophyllum trabeum*, *Rhodonia (Postia) placenta*) (Gilbertson, 1980). In contrast to white-rot fungi, brown-rot species modify lignin through non-enzymatic breakdown. They have evolved from ancestral white-rot lineages several times with subsequent reduction in key plant biomass degrading enzymes (Arantes *et al.*, 2011; Floudas *et al.*, 2012). It is estimated that only 7% of wood decaying fungi are brown-rotters (Hatakka and Hammel, 2010). They primarily attack the polysaccharide fraction of wood, whereas lignin is only modified e.g., by demethoxylation. The residual lignin is dry, brown and has decreased strength resulting in its breaking into cubical cracks (Akhtar *et al.*, 1997; Hammel, 1997). Brown-rot fungi modify the plant cell wall by oxidative radical based system with secretion of iron-sequestering oxalate (Espejo and Agosin, 1991; Zhu *et al.*, 2016).

Oxygen-derived free radicals, such as hydroxyl radical ($\cdot\text{OH}$), generated in Fenton reaction ($\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \text{OH}^- + \cdot\text{OH}$) diffuse into the wood. Lignocellulose is disrupted by attack of $\cdot\text{OH}$ leading to rearrangement of lignin by depolymerization, repolymerization and demethylation resulting with conformational changes in its structure (Arantes *et al.*, 2011; Goodell *et al.*, 1997).

Grey-Rot Fungi

Based on the analysis of the basidiomycete genomes, reclassification of wood rot types has been suggested (Floudas *et al.*, 2012; Nagy *et al.*, 2016; Riley *et al.*, 2014). The continuum of fungal decay strategies has been observed by species with intermediate wood decay mechanism such as *Schizophyllum commune*, *Jaapia argillacea* and *Botryobasidium botryosum*. These so-called grey-rot fungi resemble brown-rot species by lacking class II heme peroxidases, but still having diverse enzymes for cellulose degradation typical for white-rot fungi. Also some ectomycorrhizal fungi (ECM) have shown decay strategies similar to wood-decaying fungal species. Radical-based oxidation mechanism similar to brown-rot fungi has been reported in *Paxillus involutus* (Rineau *et al.*, 2012). Although most ECM have few or no class II heme peroxidases, gene repertoire of some ECM such as *Cortinarius glaucopus* and *Hebeloma cylindrosporum* suggest that they are able to produce white-rot (Bödeker *et al.*, 2014; Kohler *et al.*, 2015).

Soft-Rot Fungi

Soft-rot causing fungi are ascomycetes (e.g., *Daldinia*, *Chaetomium* and *Trichoderma* species) that mainly attack cellulose fraction of wood, but are also able to convert lignin to some extent (Hatakka and Hammel, 2010). They are mostly soil-inhabiting species, which degrade wood in wet environments. These fungi typically colonize hardwood resulting with brown, soft and sponge-like appearance. Soft-rot species are able to demethylate lignin, but relatively little is known about their enzymatic system (Osuno, 2020; Venkatesagowda, 2019). Species in the Xylariaceae family have been shown to decompose wood lignocellulose by cellulases, xylanases and laccases, but they lack lignin-modifying peroxidases required for efficient mineralization of lignin (Blanchette, 1995; Liers *et al.*, 2011; Nagy *et al.*, 2016).

Table 1 Division of fungal lignin-modifying peroxidases and H₂O₂-producing enzymes addressed in this article into (sub)families of auxiliary activities (AA) in the CAZy database

CAZy (sub)family	Enzyme name	Enzyme abbreviation	EC number
AA2	<i>Class II peroxidases</i>		
	Manganese peroxidase	MnP	EC 1.11.1.13
	Lignin peroxidase	LiP	EC 1.11.1.14
	Versatile peroxidase	VP	EC 1.11.1.16
AA3	<i>Glucose-methanol-choline oxidoreductases (GMCs)</i>		
AA3_2	Aryl-alcohol oxidase	AAO	EC 1.1.3.7
	Glucose oxidase	GOX	EC 1.1.3.4
AA3_3	Methanol oxidase/Alcohol oxidase	MOX/AOX	EC 1.1.3.13
AA3_4	Pyranose 2-oxidase	POX, P2O	EC 1.1.3.10
AA5	<i>Copper radical oxidases (CROs)</i>		
AA5_1	Glyoxal oxidase	GLX, GLOX	EC 1.1.3.15
AA5_2	Galactose oxidase	GAO	EC 1.1.3.9
	Raffinose oxidase	RaOx	EC 1.1.3.-
	Alcohol oxidase	AlcOx	EC 1.1.3.13
AA7	<i>Glucoligosaccharide oxidase</i>	GOOX, GOO	EC 1.1.3.-

Class II Fungal Heme Peroxidases

The biological modification of lignin is possible because of a wide array of extracellular oxidoreductases produced by fungi, especially by the wood- and litter-degrading white-rot species. The main lignin-modifying enzymes, which are widespread among white-rot fungi, include lignin peroxidases (LiPs), manganese peroxidases (MnPs) and versatile peroxidases (VPs), together with other oxidoreductases (Table 1). These enzymes have biotechnical interest, not only because of their ability to degrade and modify lignin, but also due to their potential to oxidize other recalcitrant compounds, including both organic and inorganic compounds. Most of these enzymes are classified as auxiliary activities (AA) in the CAZy database (See “Relevant Websites section”) according to their structural similarity (Lombard *et al.*, 2014). Other peroxidase enzymes possibly involved in fungal lignin degradation are members of heme thiolate peroxidase (HTP) superfamily, including e.g., chloroperoxidases and peroxygenases, and dye-decolorizing peroxidases (DyPs). Comprehensive information about these enzymes is reviewed by e.g., Hofrichter *et al.* (2015) and Linde *et al.* (2015). Furthermore, we do not address laccases in this chapter, as they are described in detail e.g., in Canas and Camarero (2010).

Besides fungi, peroxidase enzymes are found in other micro-organisms, plants and animals. The lignin-modifying peroxidases belong to class II secreted fungal peroxidases, which are members of the non-animal peroxidase superfamily (Hofrichter *et al.*, 2010). In the CAZy database, fungal lignin-modifying peroxidases belong to AA2 family. The non-animal peroxidase superfamily also includes class I intracellular non-animal peroxidases and class III classical secreted plant peroxidases (Hofrichter *et al.*, 2010; Welinder, 1992). Class II peroxidases catalyze oxidation of numerous substrates using hydrogen peroxide or organic peroxides as electron acceptor while water is produced as a by-product. In the multistep reaction, two electrons are derived from substrate molecules to reduce the enzyme and two water molecules are released. Consequently, organic radicals are formed, which rapidly undergo further chemical reactions leading to formation of oxidized or coupled (oligomeric) products (Fig. 1).

Manganese Peroxidase

The ligninolytic ability of manganese peroxidases (MnPs) is based on their ability to oxidize Mn(II) to Mn(III) that form chelated complexes with organic acids such as oxalate, fumarate and malate. The chelated Mn(III) serves as a freely diffusible oxidant, a mediator, which penetrates into the wood cell wall and begin the decay process by oxidizing phenolic substructures in lignin via formation of phenoxyl radicals. These radicals further react to yield various breakdown products (Hofrichter, 2002). Consequently, this further allows the invasion of enzyme molecules into wood (Blanchette *et al.*, 1997). Besides phenolic lignin substructures and dimers, the Mn(III) is able to catalyze the oxidation of phenolic substrates, such as phenols, amines, dyes (Wong, 2009). Since Mn (III) chelate is a mild oxidant, it is not capable of oxidizing non-phenolic lignin units that form up to 90% of the lignin polymer (Popp and Kirk, 1991). MnPs have been shown to oxidize these structures by some mediators or co-oxidants, such as thiols, unsaturated fatty acids and their derivatives (Bermek *et al.*, 2002; Jensen *et al.*, 1996; Kapich *et al.*, 1999; Wariishi *et al.*, 1989).

Lignin Peroxidase

Lignin peroxidase (LiP) is a ligninolytic enzyme, which is relatively nonspecific to its substrates and a wide array of oxidations, all of which are dependent on H₂O₂, have been confirmed (Hammel *et al.*, 1993; Kirk and Farrell, 1987). The efficient oxidation of nonphenolic aromatic compounds without participation of mediator molecules distinguishes LiPs from MnPs. The oxidation products of non-phenolic lignin structures are highly reactive aryl cation radicals that further undergo a variety of non-enzymatic

Fig. 1 The peroxidase substrate presented includes a typical ether substructure, which represents the major linkage (β -O-4 linkage, 90%) in natural lignins. Benzyl alcohol derivatives ($R = H$ or OCH_3) are substrates for aryl-alcohol oxidase, a member of the glucose-methanol-choline (GMC) oxidases. Methylglyoxal is a substrate for glyoxal oxidase, a member of the copper radical oxidases (CROs). These enzymes have significant role in producing H₂O₂, which is the electron acceptor used by peroxidases. Schematic illustration of oxidative mechanisms involving class II peroxidases and H₂O₂-producing enzymes in the lignin modification (adapted from Cullen, D., 2013. Wood decay. In: Martin, F. (Ed.), *The Ecological Genomics of Fungi*. Hoboken, NJ: John Wiley & Sons, Inc. pp. 43–62).

reactions, such as cleavage of C $_{\alpha}$ -C $_{\beta}$ side chains of lignin and demethylation (Lundell *et al.*, 1993; Schoemaker *et al.*, 1985). LiPs convert wide range of phenolic substrates to phenoxyl radicals, which subsequently react to form ring-cleavage products or lead to a variety of reactions (Harvey *et al.*, 1993). The reactions result in many different products dependent on substrate structure. In addition, LiPs can oxidize several other substrates including veratryl alcohol (Hammel *et al.*, 1993).

Versatile Peroxidase

Versatile peroxidase (VP) combines the catalytic properties of MnP and LiP, and is able to oxidize their respective substrates (Ruiz-Dueñas *et al.*, 2009). Thus, similar to MnPs, VPs can oxidize Mn(II) to Mn(III), and additionally, they can oxidize non-phenolic lignin structures or substrates such as veratryl alcohol, without addition of Mn, like LiPs (Mester and Field, 1998). VPs demonstrate different pH optima for the two types of enzyme activities: the optimal pH for Mn(II) oxidation is around 5, while pH 3 is the optimum for the oxidation of aromatic compounds. These optimum pH values are close to the corresponding pH values observed for MnPs and LiPs, respectively (Martínez, 2002).

Structural Properties of Class II Peroxidases

The class II peroxidases are globular proteins with two calcium-binding sites (Fig. 2) and usually have eight cysteine residues forming four disulfide bonds (MnPs have five) providing additional stability for the secreted enzymes (Martínez, 2002). The active electron transfer center of the peroxidases is the iron-containing heme (protoporphyrin IX) which binds hydrogen peroxide or less reactive organic peroxides (Hofrichter *et al.*, 2010). Heme is buried in the interior of the enzyme and has access to the outer medium through two channels (Ruiz-Dueñas and Martínez, 2009). The main channel found in all class II peroxidases, is used by H₂O₂ and small molecule substrates. In the second site, Mn(II) is oxidized to Mn(III) by VP and MnP. MnPs have a Mn-binding site formed by three acidic residues near the heme propionates (Blodig *et al.*, 2001; Kishi *et al.*, 1996; Sundaramoorthy *et al.*, 1994, 2005). LiPs have a solvent-exposed tryptophan radical center, and VPs have both the Mn-binding site and solvent-exposed tryptophan (Doyle *et al.*, 1998; Mester *et al.*, 2001; Perez-Boada *et al.*, 2005; Ruiz-Dueñas *et al.*, 2009). In MnP and VP, acidic residues (Glu, Glu and Asp) form the Mn-binding site, whereas in LiP one of these residues is present (Glu), but the two others are

Fig. 2 Ribbon models for the molecular structures of class II peroxidases. (A) A manganese peroxidase (MnP) from *Phanerochaete chrysosporium* (image of Protein Data Bank (PDB) ID 3M5Q). (B) A versatile peroxidase (VP) from *Pleurotus eryngii* (image of PDB ID: 2BQJ). (C) A lignin peroxidase (LiP) from *P. chrysosporium* (image of PDB ID: 1LGA). The green spheres are structural Ca(II) ions in extracellular heme peroxidases. The substrate, Mn(II), near the heme, is indicated (violet sphere) for MnP and VP. Residues of catalytic solvent exposed tryptophan (VP: Trp164, LiP: Trp171) and buried heme cofactor (orange sphere: Fe) with two axial conserved histidines (MnP: His46, His173, VP: His47, His169, LiP: His47, His176) are indicated. The heme pocket of lignin-modifying peroxidases includes also other conserved residues not indicated in the figure but reviewed by Martínez. replaced by neutral residues (Ala and Asn) accordingly with the absence of the Mn(II)-binding site in these enzymes (Sigoillot *et al.*, 2012). The surface tryptophan of LiPs and VPs has a role in direct oxidation of the non-phenolic moiety of lignin by abstracting electrons from lignin and transferring them to heme via a long range-electron transfer (LRET) pathway (Doyle *et al.*, 1998; Mester *et al.*, 2001; Sáez-Jiménez *et al.*, 2015, 2016). This mechanism is beneficial because lignin polymers as well as various aromatic substrates cannot penetrate inside the protein to transfer electrons directly to the heme cofactor.

Evolutionary Background of Class II Peroxidases

The evolution and diversity of the class II peroxidases have been thoroughly studied in white-rot fungi. Evolutionary reconstruction and comparative genomic studies have shown that these enzymes share a non-ligninolytic peroxidase ancestor, which was further evolved so that the origin of fungal lignin biodegradation occurred in the late Carboniferous period (Floudas *et al.*, 2012; Nagy *et al.*, 2016). Duplications of the genes, possibly as a part of genome-size expansion, occurred after the appearance of the first white-rot species (Nagy *et al.*, 2016) and the evolutionary process continued and resulted in appearance of several subfamilies of ligninolytic peroxidases (Ruiz-Dueñas *et al.*, 2013). The class II peroxidases have evolved through several stages: first from MnP to gaining the catalytic tryptophan at the protein surface, thus generating VP enzymes, and following with the loss of Mn(II)-binding site resulting in the evolution of LiP enzymes (Ruiz-Dueñas *et al.*, 2013). Thus, MnPs are the most common lignin-modifying peroxidases present in the white-rot fungal genomes, while LiP encoding genes have been described from only a few genera (Floudas *et al.*, 2012).

In experimental studies, the appearance of the catalytic tryptophan (VP, LiP) has been demonstrated to increase the stability of the enzymes at low pH values, which is a key feature for enzymes acting under the acidic conditions that occur during lignin decay in nature (Ayuso-Fernández *et al.*, 2017, 2018). Besides increased stability at acidic pH, redox properties of these peroxidases have improved after the appearance of the catalytic tryptophan (Ayuso-Fernández *et al.*, 2019a). These both changes have endowed white-rot fungi with more efficient lignin degradation ability. In addition, it has been suggested that the evolutionary appearance of catalytic tryptophan residue occurred parallel to the appearance of angiosperms (hardwood trees) that have more complex and less phenolic lignin compared to gymnosperms (softwood trees) (Ayuso-Fernández *et al.*, 2019b). Overall, white-rot fungi have been specialized on angiosperm hosts during the evolution, while brown-rot fungi, without class II peroxidases, have become more generalist (Krah *et al.*, 2018).

H₂O₂-Producing Enzymes

Hydrogen peroxide is one of the key metabolites in lignocellulose degradation as it e.g., acts as an electron acceptor in the reactions catalyzed by lignin-modifying heme peroxidases (Fig. 1) (Martínez *et al.*, 2009). More recently, lytic polysaccharide monooxygenase (LPMO) activity was shown to be driven by H₂O₂ (Bissaro *et al.*, 2017), thus assisting in the oxidative cleavage of polysaccharides. H₂O₂ also plays an important role as a precursor for hydroxyl radical formation by Fenton reaction, which is a non-enzymatic approach for lignocellulose degradation especially in brown-rot fungi (Daniel *et al.*, 2007). In line with this, extracellular H₂O₂-producing enzymes from several AA (sub)families, representing glucose-methanol-choline (GMC) and copper radical oxidase (CRO) enzyme superfamilies (Table 1), are widely present in the basidiomycete white-rot, brown-rot and grey-rot fungi, as well as in ascomycete plant biomass degrading species (Ferreira *et al.*, 2015; Kjærboelling *et al.*, 2020; Riley *et al.*, 2014; Vesth *et al.*, 2018). This reflects the general importance of H₂O₂ in different fungal approaches for lignocellulose conversion, regardless of the decay type or fungal taxonomy. However, the abundance of the H₂O₂-producing enzymes encoding genes in the fungal genomes appears to be highly variable. While their exact roles in the degradation process are mostly unknown, these enzymes and the corresponding genes are often shown to be produced and expressed at the same time with lignin-modifying peroxidases when fungi are cultivated on plant biomass (e.g., Daly *et al.*, 2018; Fernandez-Fueyo *et al.*, 2012; Miyauchi *et al.*, 2017; Rytioja *et al.*, 2017). This further supports the essentiality of H₂O₂ production in fungal lignocellulose conversion. Interestingly, recent observations suggest that H₂O₂ can also be produced by laccase-catalyzed oxidation of lignin, which may provide new options for the use of redox enzymes in biomass applications (Perna *et al.*, 2020).

Glucose-Methanol-Choline Oxidoreductases

The family of glucose-methanol-choline (GMC) oxidoreductases, first described by Cavener (1992), contains structurally homologous proteins from various organisms with diverse catalytic activities (Sützl *et al.*, 2019). All GMC oxidoreductases share a common fold and possess a covalently or non-covalently bound flavin adenine dinucleotide (FAD) as a cofactor, and their structure typically contains a FAD-binding domain and a substrate-binding domain. GMC superfamily includes several fungal extracellular enzymes that catalyze the formation of H₂O₂ and are therefore likely involved in degradation of native lignocellulose polymers. These members are cataloged in AA3_2, AA3_3 and AA3_4 subfamilies in the CAZy database.

Aryl-alcohol oxidases (AAOs) are members of the CAZy AA3_2 subfamily and they catalyze the oxidation of lignin-derived compounds, such as phenolic aromatic acids and other aromatic fungal metabolites, to their corresponding aldehydes by concomitantly reducing O₂ to H₂O₂ (Hernández-Ortega *et al.*, 2012a). AAOs are monomeric, two domain containing enzymes (Fig. 3) that have non-covalently bound FAD in their structure (Ferreira *et al.*, 2015). These enzymes are abundantly encoded by white-rot fungal genomes, and detailed investigations have especially been concentrated in AAOs from different *Pleurotus* species (Bourbonnais and Paice, 1988; Guillén *et al.*, 2000; Sannia *et al.*, 1991).

Another representative of AA3_2 subfamily is glucose oxidase (GOX) that is structurally related to AAO and catalyzes oxidation of glucose at the C1 position to corresponding lactone by reducing O₂ to H₂O₂ (Ozimek *et al.*, 2005). GOX enzymes are less prevalent in basidiomycete fungi compared to ascomycetes (Ferreira *et al.*, 2015). Therefore, GOX has mostly been studied in

Fig. 3 Ribbon models for the molecular structures of two glucose-methanol-choline (GMC) oxidoreductases. (A) Aryl-alcohol oxidase (AAO) from *Pleurotus eryngii* (image of PDB ID 3FIM). (B) Pyranose oxidase (POX) from *Trametes multicolor* (image of PDB ID 3BG6). POX is a tetrameric protein with one FAD cofactor molecule per monomer. The FAD molecules are represented as stick models. UCSF Chimera was used for graphical analysis and image generation. ascomycete species, such as *Aspergillus niger*, especially regarding its biotechnological potential (see Section “Potential Applications of Fungal Lignin-Modifying Peroxidases and H₂O₂-Producing Enzymes”), and its role in lignocellulose degradation is not certain.

Methanol oxidase (MOX), also known as alcohol oxidase (AOX), is classified in the CAZy AA3_3 subfamily. MOX oxidizes methanol that is produced from lignin-derived phenolic substances by demethoxylation (Ander *et al.*, 1985). While the abundance of the MOX encoding genes seems to be equal in white- and brown-rot fungi (Ferreira *et al.*, 2015), it is worth to mention that MOX has especially been indicated as an important activity in brown-rot fungi (Martinez *et al.*, 2009), as MOX is possibly the main supplier of H₂O₂ for Fenton-chemistry based brown-rot wood decay. MOX enzymes have been characterized e.g., from the white-rot species *P. chrysosporium* (Nishida and Eriksson, 1987), and the brown-rot species *G. trabeum* (Daniel *et al.*, 2007).

The most distantly related enzymes of the CAZy AA3 family are pyranose oxidases (POX, P2O) that are cataloged to the subfamily AA3_4 (Sützl *et al.*, 2018). POX is a homotetramer (Fig. 3) and does not possess similar level of conservation of typical motifs that are present in the other AA3 family members. These enzymes catalyze oxidation of various aldopyranoses at C2 position resulting in the formation of the corresponding 2-ketoaldoses (Sützl *et al.*, 2018). POX has been investigated in detail in *P. chrysosporium* (de Koker *et al.*, 2004; Pisanelli *et al.*, 2009) as well as in another white-rot fungus, *Trametes multicolor* (syn. *Trametes ochracea*) (Leitner *et al.*, 2001). POX is widely present in wood-degrading basidiomycete fungi and it has been detected both extracellularly and in the hyphal periplasm (Daniel *et al.*, 1992).

Copper Radical Oxidases

Fungi also possess extracellular H₂O₂-producing enzymes that belong to the superfamily of copper radical oxidizes (CROs) (Whittaker *et al.*, 1996) and are classified in the CAZy family AA5. The most studied CRO of wood-degrading basidiomycetes is glyoxal oxidase (GLX) from the subfamily AA5_1, which is commonly present in these species. GLX produces H₂O₂ and carboxylic acids by catalyzing oxidation of broad array of substrates including simple aldehydes, and α -hydroxycarbonyl and α -dicarbonyl compounds, some of which are released during lignocellulose degradation (Whittaker *et al.*, 1996). Temporal correlation of GLX with lignin-modifying peroxidases in the ligninolytic cultures of *P. chrysosporium* was reported early on (Kersten, 1990; Kersten and Kirk, 1987; Kirk and Farrell, 1987). This is further supported by the clustering of LiP and CRO encoding genes in the *P. chrysosporium* genome (Martinez *et al.*, 2004).

Galactose oxidase (GAO) from the subfamily AA5_2 is another representative of CROs. GAOs oxidize several carbohydrates as well as primary alcohols to the corresponding aldehydes with the concomitant reduction of O₂ to H₂O₂. Biological function of these enzymes is unknown and their encoding genes are relatively rarely present in the fungal genomes. In addition, two subfamily AA5_2 alcohol oxidases (AlcOx) with activity towards aliphatic primary alcohols have been characterized from the plant pathogenic ascomycete species *Colletotrichum graminicola* and *Colletotrichum gloeosporioides* (Yin *et al.*, 2015). A role in plant cell wall degradation was suggested for these enzymes, although the natural substrate of them has not yet been identified. Another example of a subfamily AA5_2 member is a raffinose oxidase (RaOx) from *C. graminicola*, which uses the trisaccharide raffinose as its preferred substrate (Andberg *et al.*, 2017). Interestingly, a recent study showed that another AA5_2 paralog from *C. graminicola* oxidizes aryl alcohols to the corresponding aldehydes, thus describing AAO activity in the family AA5 (Mathieu *et al.*, 2020). More biochemically characterized AA5 members are needed to fully reveal the versatile activities of the fungal enzymes classified to this CAZy family.

Glucooligosaccharide Oxidases

Glucooligosaccharide oxidases (GOOX) are AA7 family extracellular enzymes that are primarily active on glucooligosaccharides, but their activity on xylooligosaccharides has also been shown (Vuong *et al.*, 2013). AA7 GOOXs oxidize C1 hydroxyl groups of various carbohydrates with the concomitant reduction of O₂ to H₂O₂. The biological role of these enzymes is still ambiguous, but they have been suggested to be involved in conversion or detoxification of lignocellulose-derived compounds (Levasseur *et al.*, 2013).

Potential Applications of Fungal Lignin-Modifying Peroxidases and H₂O₂-Producing Enzymes

Fungal enzymes described in this chapter have potential applications in various industries including food, polymer, and pulp and paper, as well as in bioremediation, synthetic chemistry and biosensor applications. Examples of potential applications of these enzymes in various industries are presented in Table 2. Enzymes utilized in applications are derived from variety of fungal sources, also other than wood-decaying fungi. However, the white-rot fungi and their peroxidases have been studied for utilization in lignin removal in the pulp and paper industry. Besides lignin, these enzymes can be used to convert variety of compounds, because of their lack of substrate specificity. The high redox potential and mode of action via the generation of radicals enables lignin-modifying peroxidases to degrade wide range of xenobiotics and organic compounds.

Various dye decolourization studies of lignin-modifying peroxidases have used either immobilized or soluble enzymes. Immobilization of enzymes using different coupling techniques usually stabilize enzymes and may enhance the activity, recovery and reuse of the enzyme (Gasser *et al.*, 2012). In addition, co-immobilization of several enzymes may be used for enhanced degradation. Peroxidases are inactivated by very high concentrations of their co-substrate H₂O₂, which may be problematic in various biocatalysis and biosensor applications. For the controlled release of H₂O₂, both LiP and MnP have been co-immobilized with GOX that continuously produces H₂O₂ upon oxidizing glucose and thus minimize inactivation of peroxidases by H₂O₂.

Table 2 Examples of potential applications of lignin-modifying peroxidases and H₂O₂-producing enzymes. Some of the applications may also include other enzymes that are not indicated in the table

(Qiu *et al.*, 2009; Van Aken *et al.*, 2000). Similarly, GLOX has been utilized as H₂O₂-supplying enzyme for decolorization of malachite green in combination with MnP (Son *et al.*, 2012). Besides co-immobilization, enzymes can be cross-linked for improved modification of the substrate. VP has been cross-linked with laccase and GOX, and the ability of the aggregate to eliminate a wide range of pharmaceutically active compounds in municipal wastewaters has been demonstrated (Touahar *et al.*, 2014).

The biosensors are broadly used in the clinical applications, food industry and monitoring of environmental contaminants. The first enzyme sensor was proposed by Clark and Lyons (1962), in which GOX and an oxygen electrode were employed for glucose monitoring. Ever since, extensive research has been conducted to develop GOX-based devices for self-monitoring of blood glucose levels and continuous glucose monitoring in management of diabetes (Ferri *et al.*, 2011), as well as for monitoring of glucose in food industry (Mello and Kubota, 2002). AOXs from different yeast species have been employed in various enzyme-based alcohol biosensors. These biosensors can be used to detect alcohol in several areas including forensic and clinical analyzes as well as in food and fermentation industries (Hooda *et al.*, 2018). Also peroxidases may be used in biosensors which monitor contaminants in natural environments. LiP-graphite electrode system has been developed for detection of polyphenols, lignin and lignin model compounds (Ferapontova *et al.*, 2006). The immobilized LiP demonstrated significant bioelectrocatalytic activity for the reduction of H₂O₂ by oxidizing lignin model compounds. The bioelectrocatalytic properties of VP (Munteanu *et al.*, 2005) and MnP (Ferapontova *et al.*, 2002; Petruccioli *et al.*, 2009) enzymes have also been promising. Biosensors based on the use of GAO can be used for determination of galactose in clinical chemistry, food and fermentation industries (Kanyong *et al.*, 2013; Sharma *et al.*, 2006). In addition, GAO-catalyzed oxidation of mono- and oligosaccharides, e.g., for synthesis of alcohols or amines, and production of H₂O₂ and reactive oxygen species, has been the basis of several patents and patent applications (reviewed by Parikka *et al.*, 2015).

Overall, H₂O₂-producing enzymes have been shown to be promising biocatalysts for the synthesis of valuable chemicals. Although AAO mainly catalyzes the oxidation primary benzyl alcohols, AAO variant oxidizing S-enantiomer of secondary aryl-alcohol has been obtained by protein engineering (Serrano *et al.*, 2019). The production of enantiomerically-enriched secondary alcohols is of commercial interest since chiral secondary alcohols are highly valuable building blocks (Hernández-Ortega *et al.*, 2012b). They can be used as starting materials for the synthesis of various enantiomerically pure compounds for pharmaceutical industry.

The utilization of GOX is not restricted to glucose sensors, and it is used as an analytical reagent in glucose assay kits (Giampietro *et al.*, 1982) and in clinical glucose analyzers (Heller and Feldman, 2008). In addition, GOX may be used for example in dry egg powder, wine and gluconic acid production as well as in breadmaking and as a food preservative or antimicrobial agent (Dubey *et al.*, 2017). These applications rely on the ability of GOX to remove glucose and O₂ or production of gluconic acid and H₂O₂. The diverse use has been possible since GOX is Generally Regarded As Safe and these enzymes are commercially available from several enzyme companies (Wong *et al.*, 2008). Noteworthy is that also LiP has been trademarked as Melanozyme and known on the market as Elure products (See "Relevant Websites section") of Rakuto Bio Technologies Ltd. for the treatment of hyperpigmentation and skin brightening (Belinky *et al.*, 2014; Draelos, 2015).

Concluding Remarks

Fungal degradation and conversion of plant biomass is an important process in nature. Due to this ability, fungi and their enzymes are also highly relevant for the development of bio-based economy, and they have gained increasing attention as potential candidates for several bioprocesses. However, the large-scale recombinant production of lignin-modifying peroxidases is a bottleneck that hinders the biotechnological use of these enzymes. In addition, the limitations of genetic manipulation of basidiomycetes as well as the lack of knowledge regarding the regulation of lignocellulose degradation restricts use of these fungi for homologous production of lignocellulose converting enzymes. Still, the recent developments in genome editing techniques may open up new avenues for the production of individual lignin-modifying enzymes in basidiomycetes. Protein engineering and process optimization are also needed to up-scale the potential applications of ligninolytic peroxidases and H₂O₂-producing enzymes to industrial level. Due to the multiplicity of these enzymes in fungi, elucidation of the differences in the biochemical, structural and operational properties, such as catalytic efficiency and stability, of the individual enzymes would be highly beneficial, to be able to select the most suitable candidates for specific applications.

Fungal Peroxygenases – A Versatile Tool for Biocatalysis

René Ullrich, Alexander Karich, and Martin Hofrichter, TU Dresden, International Institute Zittau, Zittau, Germany

Introduction

Fungi (Mycota) represent a separate kingdom within the domain of eukaryotic organisms, which heterotrophically subsist due to the lack of chlorophyll and plastids and which do exclusively feed on dissolved nutrients (osmotrophy) because of the presence of rigid cell walls. Most fungi colonize terrestrial ecosystems and unlike their phylogenetic sister-group – the Metazoa (animals) – they are incapable of active motility (Moore *et al.*, 2011); this particularly applies to their trophic (vegetative) states, which do not serve reproduction. In consequence, “sessile” fungi cannot avoid negative effects of local (micro-environmental) conditions and must somehow counteract them *in situ*.

Fungi compete with prokaryotes in most ecosystems, in first place with heterotrophic eubacteria, such as *Bacillus* and *Pseudomonas* spp. A potential advantage of fungi over such unicellular prokaryotes is their capability of more efficiently disintegrating complex polymeric carbon-compounds including lignin-incrusted materials such as wood by means of secreted enzymes (digestion biocatalysts). The processes of decomposing such nutrients are “biochemically costly” and time-consuming, but are compensated by the intensive exchange of substances within the hyphal networks (mycelia) and plectenchyma, i.e., the rather slowly osmotically resorbed nutrients are going to be rapidly distributed within the whole fungal organism, so far there are nutrient gradients between the different parts of a mycelial colony (Moore *et al.*, 2011; Daly *et al.*, 2020). The most prominent example therefore is the substantial degradation of lignocelluloses, which is essential to maintain the global carbon cycle and cannot be accomplished by other organisms including bacteria (Floudas *et al.*, 2012). Several types of extracellularly acting enzymes are the prerequisite to get access to lignocelluloses (wood, leaf-litter, humus fractions) as carbon sources, some of which, such as manganese(II)-oxidizing peroxidases (MnPs), lignin peroxidase (LiP), aryl-alcohol oxidases (AAOs) and lytic polysaccharide monooxygenases (LPMOs), have exclusively evolved within the fungal kingdom (Note, there are a few examples of LPMOs in bacteria but they are chiefly associated with chitin degradation).

Unspecific peroxygenases (UPOs) represent another example of enzymes that exclusively occur in fungi (The few exceptions such as *Phytophthora* *et al.* will be discussed later), even though their natural and physiological functions have not been fully understood yet. UPOs are heme-thiolate proteins, which transfer peroxide-borne oxygen to diverse organic compounds. Regarding these properties, they resemble P450 monooxygenases (P450s) occurring in all domains of life, which, however, typically use dioxygen (O₂) and external electron donors (NAD[P]H). Unlike the P450s that are intracellular (cytosolic or membrane-bound) biocatalysts, most UPOs are extracellular enzymes, which fungi actively secrete (Hofrichter *et al.*, 2010).

Upadhyay first mentioned an unusual “alkaline lignin peroxidase” that was produced by the agaric fungus *Agrocybe aegerita* (*Cyclocybe aegerita*) in liquid culture (Upadhyay, 1995). Almost ten years later, this enzyme was described as *A. aegerita* peroxidase (AaP) and – for the time being – classified as a haloperoxidase due to brominating activities and homology of the *N*-terminus to that of chloroperoxidase [CPO = *Lfu*UPO from *Caldariomyces fumago* (*Leptoxylum fumago*); (Ullrich *et al.*, 2004)]. Then, in 2005, it was shown that AaP is capable of hydroxylating toluene and naphthalene (Ullrich and Hofrichter, 2005), while subsequent studies demonstrated further oxyfunctionalizations, in first place of aromatic substrates (Ullrich and Hofrichter, 2007; Aranda *et al.*, 2009, 2010). Therefore, the enzyme (AaP) was re-named into aromatic peroxygenase (APO), taking also into account that oxygen transfer was favored over peroxidation (Hofrichter *et al.*, 2010). Eventually, because of diverse further oxyfunctionalisations, e.g., hydroxylation of *n*-alkanes and cycloalkanes, epoxidation of alkenes, heteroatom oxygenation of *S*- and *N*-heterocycles, it was reasonable to supplement the enzyme classification system (EC nomenclature) by a new entry: the sub-subclass of the “peroxygenases” that act with H₂O₂ as electron acceptor, one oxygen of which is incorporated into the product (EC 1.11.2.-; Hofrichter and Ullrich, 2014). Enzymes of this sub-subclass transfer oxygen from peroxides (O-donor) to various substrates; thus, they actually represent a special type of monooxygenase. Meanwhile, peroxygenases secreted by fungi are classified as the first entry within this sub-subclass under EC 1.11.2.1 (unspecific peroxygenase, UPO) (Hofrichter and Ullrich, 2014). Further representatives are myeloperoxidase of neutrophilic granulocytes of Chordata (EC 1.11.2.2), plant-seed peroxygenase of Spermatophyta (EC 1.11.2.3) or bacterial fatty-acid peroxygenase (EC 1.11.2.4) (Fig. 1).

Although UPOs peroxygenate various substrates, the catalyzed reactions proceed stereoselectively and often even enantioselectively. Moreover, most UPOs studied show a remarkable insensitivity towards pH, organic solvents and other physicochemical factors, which makes them interesting candidates to be used in biotechnology, organic synthesis and bioremediation.

In this chapter, we summarize and review the state of knowledge on fungal UPOs with focus on the reaction cycle and structural aspects. Furthermore, the catalyzed reactions are surveyed including selective oxyfunctionalisations. CPO (chloroperoxidase; EC 1.11.1.10, Fig. 1) that is actually a UPO, from the phylogenetic point of view (“*Lfu*UPO”), is considered here to some extent. However, we want to point to several comprehensive articles specifically dealing with catalytic and structural aspects of CPO (Chen *et al.*, 2008; Dembitsky, 2003; Griffin, 1992; Manoj and Hager, 2008). We also give an overview on the homologously and heterologously producible UPOs.

Fig. 1 Biochemical classification of oxidoreductases using peroxides (R-O-O-H) as electron acceptor (EC 1.11) including all representatives of enzymes with “H₂O₂ as acceptor, one oxygen atom of which is incorporated into the product” (= peroxygenases, EC 1.11.2). Phylogenetically related fungal enzymes are marked in blue (based on Enzyme Nomenclature: <https://www.qmul.ac.uk/sbcs/iubmb/enzyme/EC1/11/>).

General Aspects

The following three subarticles describe phylogenetic aspects of UPOs, their reaction cycle, and protein structure.

Phylogeny

UPOs are widely distributed within the kingdom of Fungi, whereas no *upo* genes have been detected so far in the closest relative of Fungi – the kingdom of Nucleariæ (“Nucleariæ are lacking chitin synthase genes division II – a gene cluster that is present in all true fungi (sometimes also named ‘chitin fungi’) share” (James and Berbee, 2012)), which are nowadays designated as non-fungal opisthokonts (Kiss et al., 2019). Thus, the border between both kingdoms seemingly marks the limit in the occurrence of UPOs (Fig. 2), and hence animals (Metazoa) do not possess *upo* genes either. There are only few fungal phyla without *upo* genes or maybe, for which such genes have not yet been identified. These are all small phyla, i.e., Aphelidiomycota, Olpidiomycota, Calcarisporiellomycota or Kickxellomycota, with only eleven full genome sequences available. Larger taxonomical groups almost lacking *upo* genes are Saccharomycotina (true yeasts) and Schizosaccharomycetes (fission yeasts), which are a subphylum and a class of the Ascomycota, respectively (There is one exception: *Lipomyces starkeyi* NRRL Y-11557). These two taxa comprise highly specialized organisms with reduced genomes, which preferably dwell in sugar-rich habitats, such as nectaries or riping fruits, which likely explains their reduced genomes (Mohanta and Bae, 2015).

Apart from true fungi, *upo* genes were found in “parasitic algae” of the class of Peronosporomycetes (formerly “Oomycota” or “Oomycetes”, within the supergroup of Stramenopiles). Notably, the powdery mildew (diverse species of Erysiphales, Ascomycota) and downy mildew (diverse species of the Peronosporales, Peronosporomycetes) can share the same plant hosts. Thus, an uptake of foreign DNA by horizontal/lateral gene transfer seems to be a plausible explanation for the occurrence of *upo* genes in phytoparasitic pseudo-fungi. This may have happened to other parasitic Peronosporomycetes as well, among them feared pathogens causing the potato blight (*Phytophthora infestans*) or the crayfish plague (*Aphanomyces astaci*) (Bredeweg and Baker, 2020; Szöllősi et al., 2015).

The ancestral UPOs must have evolved near the base of true fungi (i.e., Eumycota; Fig. 2). However, the phylogeny of UPOs does obviously not fully correspond to the current fungal phylogeny. Again, this fact may be explained by horizontal gene transfer within the fungal kingdom (Szöllősi et al., 2015). UPO encoding genes are divided into two families. Whereas family I contains UPOs with relative short genes resulting in theoretical mature proteins with an average molecular mass around 30 kDa (known as “short” UPOs), family II comprises larger proteins with an average molecular mass of 44 kDa (named “long” UPOs). Members of family I occur in all UPO-positive fungal phyla, while family II *upo* genes are restricted to the super-phylum of Dikarya (Ascomycota and Basidiomycota). Roughly, half of the *upo* genes in family I does not contain predictable signal peptides. Thus, family I further splits into two clades (subfamilies) of probably intracellular and extracellular UPOs. Genes without signal peptide belong to clade I.1, but almost nothing is known about this clade (except the genomic sequences) and whether they encode functional intracellular enzymes remains unclear. Clade I.2 comprises UPO sequences with signal peptides, including the characterized ascomycetous enzymes from *Leptoxiphium (Caldariomyces) fumago* (CPO) and *Chaetomium globosum* (CglUPO) as well as the basidiomycetous peroxygenases from *Marasmius wettsteinii* (MueUPO) and *Marasmius rotula* (MroUPO) (Hofrichter et al., 2020; Kellner et al., 2016; Kiebitz et al., 2017; Ullrich et al., 2018).

Family II forms, with regard to gene sequences, a more homogeneous clade of UPOs. It contains all “long” UPOs that are present in almost all genome-sequenced genera of Ascomycota and Basidiomycota (with the exceptions mentioned above), and all of them have predicted signal peptides. All “long” UPOs described and characterized at the protein level so far belong to basidiomycetous members of family II (Tables 2 and 3; Hofrichter et al., 2015, 2020).

Fig. 2 Simplified phylogenetic tree of the kingdom of Fungi within the supergroup of Opisthokonta (modified according to Tedersoo *et al.*, 2018). Names marked in green represent eufungal phyla (suffix '-mycota') and pseudofungal Peronosporomycetes comprising species that have putative *upo* genes in their genomes. * Indicates small phyla without available genome data; ** the Peronosporomycetes (former "Oomycetes" or "Oomycota") are a class within the supergroup SAR (Stramenopiles-Alveolata-Rhizaria); K – kingdom, SK – superkingdom, SG – supergroup (i.e., unranked taxa above the kingdom level).

Besides the gene length, there are notable differences in the molecular structure between the UPO families. We will discuss these structural aspects later in the sub-chapter "Structural Insights".

Reaction Cycle

A first hypothetical reaction cycle of UPOs was already reported in 2007, and since then it has been steadily improved and substantiated (Ullrich and Hofrichter, 2007). Four relevant reactive UPO intermediates are involved in the cycle and two basic reaction routes can be distinguished. The reaction cycle combines one-electron oxidations known from "classic" peroxidases with the peroxide "shunt" pathway of P450 monooxygenases (P450s) (Denisov *et al.*, 2005; Dunford, 1999; Hofrichter *et al.*, 2015; Hrycay and Bandiera, 2015).

Both catalytic routes start with the UPO-resting state, in which the enzymes' heme iron is in the ferric state (Fe^{3+}) and weakly bound to a water molecule as distal ligand. When a peroxide molecule (e.g., H_2O_2) replaces water, a short-lived "pre-compound 0" (pCpd-0) is formed. Immediately the deprotonated carboxylic group of the side chain (pK_a 4.2) of a highly conserved glutamate accepts a proton from pCpd-0 under formation of a negatively charged ferric peroxo-complex (compound 0, Cpd-0). The negative charge of this important glutamate residue is stabilized by a conserved histidine (pK_a 6.0) or an arginine (pK_a 13.8) in the case of short UPOs and long UPOs, respectively (Piontek *et al.*, 2013; Ullrich *et al.*, 2018). Upon heterolytic cleavage of Cpd-0, a water molecule is released and compound I (Cpd-I) is formed (Fig. 3). Cpd-I corresponds to an oxo-ferryl species ($\text{Fe}^{4+}=\text{O}$) in addition with an oxidizing equivalent (cation radical, $\bullet+$) delocalized at the near heme environment. Cpd-I is the key intermediate in the reaction cycle that initiates substrate oxyfunctionalization or oxidation. The reaction sequence resembles an alternative and rarely efficient monooxygenation-route of P450s, the so-called "peroxide shunt" pathway. Unlike UPOs, the typical route of Cpd-0 formation in P450s requires two redox equivalents [mostly NAD(P)H] and dioxygen (O_2). It proceeds via three additional intermediate states: (1) an Fe^{2+} -heme-substrate complex, (2) an Fe^{3+} -superoxo complex and (3) an Fe^{3+} -peroxo-dianion complex (Fig. 4; Denisov *et al.*, 2005; Rittle and Green, 2010).

One of the possible UPO routes – the (per)oxygenation route – proceeds via abstraction of a hydrogen [H] from a substrate-carbon ($\text{R}_3\text{C-H}$), yielding a ferryl hydroxide complex (protonated compound II, HO-Cpd-II) and the corresponding substrate-radical

Fig. 3 Formation of compound I (Cpd-I) in UPO-family I (“short” UPOs) and UPO-family II (“long” UPOs; both classified under EC 1.11.2.1) as well as in P450-family CYP152 (fatty acid peroxxygenase, EC 1.11.2.4). The graphic representations show the heme in different oxidation states and with proximal cysteine, distal ligands, acid-base catalysts (glutamate or fatty acid carboxylate) and charge stabilizers (histidine or arginine).

($R_3C\bullet$; $R\bullet$ in Fig. 4). An ensuing rebound restores the enzymes’ resting state and releases the hydroxylated substrate (R_3C-OH ; ROH in Fig. 4) (Wang *et al.*, 2012, 2015). Additionally, in the (per)oxidative route (not shown in Fig. 4), Cpd-I may abstract one electron from a phenolic hydroxyl group that results in the formation of a phenoxy radical and an oxo-ferryl complex (deprotonated compound II, $O=Cpd-II$). The latter catalyzes a similar reaction to give a second phenoxy radical (upon proton and electron abstraction) and concomitantly returns to the resting state under release of a water molecule.

The preferred catalytic route is strongly determined by properties of the substrate (e.g., molecule size, chemical structure, functional groups) and of the particular UPO (characterized, for example, by redox potential, localization of the substrate-binding site, size and geometry of the heme channel), as well as of the reaction medium (pH, ion strength, organic co-solvent concentration) (Hofrichter and Ullrich, 2014). It should be noted that some substrate conversions start with aromatic oxygenation (route 1), resulting in the formation of phenolic compounds, which in turn will be oxidized according to route 2; this applies, for example, to benzene, naphthalene and related aromatic compounds.

One-electron oxidations (route 2) can be also accomplished by diverse peroxidases (EC 1.11.1) and oxidases (e.g., laccase, EC 1.10.3.2). The actual value of UPOs, however, with regard to synthetic applications, lies in their ability to perform challenging oxygenations using simply hydrogen peroxide.

Structural Insights

UPOs are heme-containing enzymes, in which the heme-iron is bound to a cysteine (proximal ligand). P450 monooxygenases share this feature with UPOs and hence, both can be subsumed under the heme-thiolate proteins (HTPs) (Hofrichter *et al.*, 2015; Omura, 2005). Almost all UPOs contain the characteristic “PCP motif” near the N-terminal site of the protein; only a small number UPOs is missing the first proline in this motif (“XCP motif”). In P450s, the cysteine ligand can be also part of a “XCP motif” (or another motif), but it is located near the C-terminus (Sundaramoorthy *et al.*, 1995). In contrast to P450s, all UPOs bear the aforementioned glutamate that acts as an acid-base catalyst during heterolytic peroxide cleavage. The few H_2O_2 -dependent P450s (e.g., P450_{BSβ}) utilize external fatty acids, e.g., palmitate, for this purpose (Fig. 5; Fujishiro *et al.*, 2011; Shoji *et al.*, 2007).

In UPOs, an Mg^{2+} cation (or Mn^{2+} in CPO) is located near one of the heme propionate residues (Piontek *et al.*, 2013; Sundaramoorthy *et al.*, 1995; Ullrich *et al.*, 2018). In this respect, UPOs resemble LiP (EC 1.11.1.14) and MnP (EC 1.11.1.13), which harbor a bivalent metal ion (Ca^{2+}) for protein stabilization. Furthermore, the latter enzyme uses manganese (Mn^{2+}) that is

Fig. 4 Reaction cycle combining the monooxygenation routes of UPOs and P450s. The left route uses H₂O₂ as electron acceptor and O-donor; UPOs, P450 peroxxygenases and P450s in the ‘shunt’ mode follow this pathway. The right route illustrates the typical P450 pathway that uses O₂ and NAD(P)H as reduced redox-partner, with following intermediates: (i) ferrous-heme substrate adduct, (ii) ferric superoxo-heme complex and (iii) ferric peroxo-heme dianion complex.

Fig. 5 Comparison of the distal sites of four different heme-thiolate proteins (HTPs), including a basidiomycetous ‘short’ UPO (*MroUPO*), a basidiomycetous ‘long’ UPO (*AaeUPO*), ascomycetous CPO (a special case of ‘short’ UPOs) and a bacterial fatty-acid peroxxygenase (H₂O₂-dependent cytochrome P450_{SP} = CYP152B1). The models show amino acid residues involved in compound 0 and compound I formation, i.e., the acid-base catalyst glutamate (Glu) and the charge stabilizers histidine (His) or arginine (Arg). In the case of CYP152B1, an external fatty acid (palmitate) replaces internal Glu. The porphyrin ring and the amino acid side chains are depicted as stick models, iron ions as red spheres. Crystal models: *MroUPO* (pdb: 5FUJ); *AaeUPO* (pdb: 2YOR); CPO (pdb: 1CPO); CYP152B1 (pdb: 3awp).

Fig. 6 Comparison of magnesium/ Mg^{2+} (manganese/ Mn^{2+}) cation binding sites of CPO and two UPOs (*MroUPO*, *AaeUPO*), which correspond to the amino acid motifs *EHDHS*, *EHDAS* and *EGDAS*, respectively. The amino acid side chains and heme propionate residues (HP6 and HP7) are depicted as stick models, metal ions as spheres (Mn^{2+} - purple, Mg^{2+} - green). Crystal structure models: CPO (pdb: 1CPO), *MroUPO* (pdb: 5FUJ), *AaeUPO* (pdb: 2YOR).

Table 1 Comparison of selected structural properties of four heme-thiolate proteins belonging to EC 1.11.2 (two UPOs, CPO and P450_{SP} fatty perxygenase). Data were calculated from the corresponding crystal structures deposited under 2YP1, 5FUJ, 1CPO and 3AWP, respectively

^gstarting at position 2, the propionates are rotated by approx. 145°.

oxidized to Mn^{3+}) as redox mediator, which is transiently bound at the same position as Mg^{2+} in UPOs. This again sets UPOs apart from P450s that do not contain any type of cation in the apoprotein (Denisov *et al.*, 2005; Nie and Aust, 1997; Poulos, 1993; Sundaramoorthy *et al.*, 1994). Note that Sundaramoorthy *et al.* (1995) suggested the presence of Mn^{2+} in CPO, which, however, could be Mg^{2+} as well (Piontek *et al.*, 2013).

In addition to the carboxylic group of one heme-propionate, two amino acid residues, a glutamate and a serine, and the carbonyl oxygen of the peptide bond between glycine (family II) or histidine (family I) and aspartate chelate the Mg^{2+} in UPOs (Fig. 6, Table 1). This difference in the Mg^{2+} ligands defines – along with the overall molecular mass – the two UPO families. In family I, histidine is complexed with the Mg^{2+} cation and thus, the corresponding chelate-motif is EHD(A)S. UPOs of family II, on the other hand, have a glycine at this position that is part of the EGD(A)S motif. Interestingly, the chelating histidine in family I has a further, even more important function. It functions as the charge stabilizer that assists deprotonation of H_2O_2 by the

Fig. 7 Tangential cross section through 3D models (crystal structure-based) of CPO, *MroUPO* and *AaeUPO* (*top row*) and enlarged sections of the respective active sites (*middle row*). Adjusted graphic representations show the heme propionates at the left with the metal cations (Mn^{2+} in purple or Mg^{2+} in green). CPO has two narrow entries to the heme-access channel, while *MroUPO* and *AaeUPO* have only one but rather wide entry. The three pictures *below* illustrate the maximum access path towards the heme in top-view. Blue color indicates phenylalanine residues, and pink color leucine and isoleucine residues.

glutamate acting as acid-base catalyst. This function of histidine (H-86 and H-105 in *MroUPO* and CPO, respectively) is taken over by arginine (R-189 in *AaeUPO*), which is not involved in Mg^{2+} chelation, in UPOs of family II (Figs. 3 and 5). Due to the different polarities of histidine and arginine, this difference may affect UPO kinetics (i.e., Cpd-0 and Cpd-I formation) but not the overall catalytic cycle (Fig. 4).

Certainly, the molecular architecture of heme-access channels and heme-cavities is of general significance for the catalytic properties of UPOs. Their molecular dimensions and amino-acid composition determine substrate selection and binding. For example, the channel of *MroUPO* resembles a large, laterally compressed funnel with an aperture of $9 \times 18 \text{ \AA}$. It is lined with several aliphatic amino acid residues (valine, leucine, isoleucine), which convey hydrophobicity and conformational flexibility to the channel. The heme-cavity contains, in addition to hydrophobic amino acids such as alanine and isoleucine, also hydrophilic glutamic acid. In contrast, the channel of *AaeUPO* is overall narrower, its “mouth” just measures $8 \times 10.5 \text{ \AA}$ and it accommodates nine phenylalanine residues. Thus, it is not surprising that the catalytic properties and substrate spectra of UPOs can considerably vary. *MroUPO* is able to oxidize relatively bulky and (cyclo)aliphatic substrates (e.g., steroids) whereas *AaeUPO* favors smaller aromatic substrates (e.g., naphthalene). CPO has two differently sized heme-access channels, a narrower and a wider one (Kühnel *et al.*, 2006), but even the wider channel ($8 \times 8 \text{ \AA}$) is smaller than those of the other two UPOs. Furthermore, various amino acids line the channels and heme pocket in CPO (Table 1, Fig. 7), which may explain its limitation in oxidizing larger substrate molecules.

Remarkably, the heme orientation in *AaeUPO* and CPO differs from that in *MroUPO* where it is turned by 180° (“flipped like a pancake”) so that the two propionates face the same direction. In consequence, the propionate chelating Mg^{2+} switches its relative position in *MroUPO* compared to *AaeUPO* or CPO (being position 6 (Numbers correspond to FISCHER numbering of heme carbons that are connected to the propionates (Moss, 1988)) and 7, respectively; Fig. 6). Whether this conformational difference has an impact on the catalytic properties of UPOs is not clear yet.

MroUPO is a physiological dimer held together by a disulfide-bridge (Olmedo *et al.*, 2017). So far, we have observed this phenomenon only for short UPOs (family I) found in the agaric genus *Marasmius* (Table 2). Since the two monomers are covalently linked via two exposed cysteines (C-227) near the C-terminus, it is plausible that long UPOs lacking such cysteines (e.g., *AaeUPO*, CPO) cannot form dimers (instead, they form an internal disulfide-bridge near the C-terminus) (Piontek *et al.*, 2013). Whether dimerization is restricted to UPOs of the Marasmiaceae or maybe widely distributed among short UPOs, and whether dimeric UPOs may be advantageous over monomeric UPOs will have to be clarified in future structure-function studies.

Applicability of UPOs

For the successful implementation of UPOs in any kind of application, the following general conditions must be met: enzyme availability, enzyme stability and gentle peroxide supply. The following subarticle deals with these conditions and points out existing shortcomings.

Wild-Type UPOs

CPO (that can be regarded as the first described UPO) was originally produced in aerated and stirred submerged cultures containing synthetic CZAPEK-DOX medium. Maximum activities (MCD units correspond to the chlorination of monochlorodimedone to dichlorodimedone (Hager *et al.*, 1966)) of 5000 U L⁻¹ were achieved between days 6 and 7. This activity corresponded to approx. 4 mg L⁻¹ CPO protein (Morris and Hager, 1966). At that time, the versatility of CPO had not been recognized and most studies dealt with chlorination reactions. Almost four decades later, the first “true” UPO could be produced with the agaric fungus *A. aegerita* (AaeUPO, also known as AaP or APO, see introduction) in a soybean-based complex medium (Ullrich *et al.*, 2004). The enzyme was present in three main isoforms, which were separable by several chromatographic steps (Ullrich *et al.*, 2009). Further screenings, over more than 15 years, used various complex media and led to the discovery of more basidiomycetous (agaric) UPOs, e.g., in the families of Strophariaceae (*Agrocybe parasitica* = *Cyclocybe parasitica*, unpublished result), Marasmiaceae (*M. rotula*, (Gröbe *et al.*, 2011), and *M. wettsteinii*, (Ullrich *et al.*, 2018)) and Psathyrellaceae (*Coprinellus radians* and *Coprinopsis verticillata*), (Anh *et al.*, 2007), and *Psathyrella aberdarensis* (Melzer *et al.*, 2018; Hofrichter *et al.*, 2020). The production of an ascomycetous wild-type UPO in appreciable amounts (apart from CPO) succeeded solely in the case of the “wallpaper mold” *Chaetomium globosum* (Kiehist *et al.*, 2017).

UPO concentrations secreted by fungi in production batches were found to vary between 2 and 600 mg L⁻¹ (Anh *et al.*, 2007; Anh, 2008; Blanke *et al.*, 1989; Gröbe *et al.*, 2011; Pickard *et al.*, 1991; Ullrich *et al.*, 2004; Table 2). Studies carried out so far have suggested that UPOs of family I are secreted at higher levels by wild-type strains than UPOs of family II. On the other hand, efforts to optimize homologous UPO production have been performed with different intensity, hence there is surely still potential to improve it further. In this context, it is also important to mention that not only the total amount of UPO protein is important but rather the specific activity towards a particular substrate, which is a measure for the “enrichment” of UPO in the culture liquid. The complex media typically used for UPO production contain varying amounts of soybean components, peptones and/or simple sugars (glucose, fructose). Though research has focused on identifying substances and conditions that specifically stimulate UPO production, it is still unknown which mechanisms trigger it. Until now, eight wild-type UPOs have been purified and characterized. Table 2 summarizes the respective data.

Recombinant UPOs

Besides wild-type UPOs, an increasing number of recombinant UPOs has been made available. Overall, UPOs from eight different species can be heterologously expressed in fungal and bacterial hosts (*Aspergillus* spp., *Saccharomyces cerevisiae*, *Pichia* (*Komagatella*) *pastoris*, *Escherichia coli*; Table 3). The Danish company Novozymes A/S was the first producing a recombinant UPO from the ink-cap *Coprinopsis cinerea* in *Aspergillus oryzae* and tested it for synthetic applications (Babot *et al.*, 2013; Lund *et al.*, 2016). Later, they produced also recombinant UPOs from the ascomycetous fungus *Humicola insolens* in the same host (Kiehist *et al.*, 2017). CPO from *Caldariomyces fumago* was already successfully expressed in *Aspergillus niger* in 2001 (Conesa *et al.*, 2001).

Miguel Alcalde and co-workers successfully applied directed evolution in *S. cerevisiae* to generate UPO-mutants with improved synthetic properties, i.e. decreased peroxidative activity (mutant Pada-I). Such variants that can be produced at larger scale in *P. pastoris* (Molina-Espeja *et al.*, 2014, 2015, 2017) are useful when the envisaged substrates or products bear phenolic groups, which would easily be oxidized via one-electron oxidation to form unwanted phenoxy radicals initiating coupling reactions. Moreover, the atom efficiency regarding H_2O_2 will increase, if less by-products are formed. This effect may be of particular interest when large-scale applications will be intended in the future.

Very recently, Martínez *et al.* have developed an expression system on the basis of *E. coli* as the host. They were able to express native and mutated UPOs from Ascomycota and Basidiomycota in this system (Carro *et al.*, 2019; Linde *et al.*, 2020). However, recombinant UPOs produced in bacteria are still limited in the obtained amounts and lacking glycosylation, which may affect physicochemical properties such as water solubility and pH stability. Therefore, for the time being, eukaryotic expression systems as that of *P. pastoris* represent the method of choice to produce UPOs (Cregg *et al.*, 2009). Nevertheless, UPO properties may also change when they are expressed in *S. cerevisiae* or *P. pastoris*. For example, the molecular mass of recombinant AaeUPO (Pada-I) increased from 45 to 46 kDa to 51–52 kDa due to over-glycosylation (Tables 2 and 3). Such different glycosylation patterns could even affect kinetic parameters, which was already demonstrated for CPO and fungal aryl alcohol oxidases (Karich *et al.*, 2018).

Despite all efforts in the field of heterologous expression, there is no commercial UPO preparation available at present. It is conceivable, however, that this bottleneck will be overcome in the near future by further improving existing expression systems and by developing new expression strategies, e.g., cell-free approaches based on isolated ribosomes (Thoring *et al.*, 2019).

pH and Temperature Stability

Most UPOs can be stored at neutral pH over long periods. For example, purified AaeUPO dissolved in phosphate buffer (pH 7.0) and stored at 4°C has a calculated half-life of 7.3 years, which can be further extended to presumed 10.5 years and 11.1 years in the presence polyethylene glycol PEG 600 and PEG 20.0000, respectively (unpublished results). Frozen in appropriate buffers, UPOs are stable over years as well without the need of adding additional stabilizers. Even at room temperature and pH 7.0, and under reaction conditions (HMF conversion), UPOs remained stable for at least one week (Carro *et al.*, 2015). Under alkaline conditions (at pH 10.0), however, some UPOs lost their activity within minutes, e.g., CraUPO and PabUPO I, whereas others, e.g., PabUPO II and III, remained active over several hours/days (Table 2) (Anh, 2008; Kimani, 2019). Vice versa, acidic pH (3.0–5.0), was also found to negatively influence the enzyme activity, which resulted in the case of CglUPO, in a half-life of only 240 min at room temperature and a decrease in the Soret band at 420 nm (Kiebitz *et al.*, 2017).

UPO Inactivation by Peroxide

Inactivation of UPOs by its co-substrate hydrogen peroxide is directly related to their intrinsic catalase side-activity, and thus dependent on the peroxide concentration in their immediate environment (reaction medium). It was shown that the pH optima of this catalase activity (AaeUPO, MroUPO, rCciUPO and CPO) are in the same range as those of their actual peroxygenating activities (Karich *et al.*, 2016; Manoj and Hager, 2001). Above or below the pH optimum, UPO activity rapidly decreases in the presence of excess peroxide (Karich *et al.*, 2016; Park and Clark, 2006). On the other hand, it turned out that the remaining peroxygenating UPO activities were higher when high levels of catalase activity were accomplished, and hence, the “true catalase reaction” of UPOs seems to be a kind of protective mechanism (“relief valve”) to prevent them from inactivation (Karich *et al.*, 2016). Peroxide inactivation is thought to proceed via the formation of UPO compound III

(Cpd-III, a superoxide-heme complex), which may appear when compound II (Cpd-II) reacts with additional peroxide. The latter can emerge, out of the ordinary peroxxygenase cycle (compare Fig. 4), after one-electron oxidation of a peroxide molecule catalyzed by compound I (Cpd-I), analogously to the action of heme-catalases (Alfonso-Prieto *et al.*, 2009; Karich *et al.*, 2016; Vidossich and Magistrato, 2014). Cpd-III in turn may react with more peroxide to form highly reactive hydroxyl radicals ($\text{HO}\bullet$), which in turn oxidize the heme to form verdoheme (Karich *et al.*, 2016). This over-all mechanism is similar to the irreversible inactivation of class-II and class-III heme peroxidases (Vlasits *et al.*, 2010).

Actually, a “real substrate” (e.g., a C-H to be hydroxylated) will always compete with another peroxide (HOO-H) for Cpd-I (Karich *et al.*, 2016). In consequence, when the local/momentary peroxide concentration is kept as low as possible – being preferably even rate limiting (or at least a magnitude lower than the substrate concentration) – UPOs can be effectively prevented from acting in the catalase mode and hence from inactivation.

Peroxide Supply

Continuous slow addition of the co-substrate H_2O_2 (or organic equivalents, R-OOH) is the most effective way to counteract inactivation of UPOs (Karich *et al.*, 2017; Ullrich *et al.*, 2008; van Deurzen *et al.*, 1997b; Ullrich *et al.*, 2004). There are four general approaches to realize gentle peroxide supply: (1) ‘mechanical’ *ex situ* peroxide supply, (2) enzymatic *in situ* generation, (3) electrochemical *in situ* generation and (4) photochemical *in situ* generation (Fig. 8; Burek *et al.*, 2019; Karich *et al.*, 2018; Krieg *et al.*, 2011; Ullrich *et al.*, 2004). Each method has its own advantages and disadvantages that are summarized in Table 4.

The simplest way to feed peroxide to an ongoing UPO reaction is the supply via pipettes (repeatedly) or pump systems, e.g., syringe pumps (Fig. 8(a)–(c)). These methods are easy to realize, ensure fast dosing and provide high flexibility regarding the H_2O_2 -concentration (Aranda *et al.*, 2009; Karich *et al.*, 2017; Ullrich *et al.*, 2004; Ullrich and Hofrichter, 2005; Ullrich *et al.*, 2008). However, the reaction volume itself limits the maximum amount of H_2O_2 that can be added. Another inevitable disadvantage consists in the basic reaction design, i.e., the local peroxide concentration in the reaction system is always highest at the point of peroxide injection where the enzyme is going to be partially destroyed (Karich *et al.*, 2016). This negative effect can be mitigated when the co-substrate level is kept at a concentration that does not harm UPO, e.g., by using a H_2O_2 -sensor (van Deurzen *et al.*, 1997b).

In situ generation of the co-substrate is without doubt the best way to prevent too high local peroxide concentrations in reaction systems (Krieg *et al.*, 2011; Pereira *et al.*, 2015; Perez *et al.*, 2009). Enzymatic approaches are very efficient in generating H_2O_2 , since they form peroxide equally distributed in the whole reaction space (Bankar *et al.*, 2009; Pereira *et al.*, 2015; Pesic *et al.*, 2018). Usually, oxidases are used and combined with appropriate substrates (e.g., glucose oxidase/EC 1.1.3.4 and glucose) to generate one molecule of H_2O_2 during the oxidation of one substrate molecule (Bankar *et al.*, 2009). Such a “simple” method, however, has the disadvantage of accumulating additional products (in the above case, for example, gluconolactone and gluconic acid) (Pereira *et al.*, 2015). When oxidases and UPOs share the same substrate(s), intelligent enzymatic cascade reactions may be established, as it has been demonstrated by the stepwise oxidation of hydroxymethylfurfural (HMF) to furandicarboxylic acid (FDCA) by UPO and aryl alcohol oxidase (AAO/EC 1.1.3.7) (Karich *et al.*, 2018). Establishing such a cascade reaction requires the detailed analysis of each reaction step catalyzed by the single enzymes involved. In the case of oxidases, the performance is often limited by the availability of dioxygen (O_2) in the reaction medium. Nevertheless, such intelligent cascade approaches have several

Fig. 8 Six different methods of peroxide (H_2O_2) supply in UPO reactions, *ex situ*: (a) stepwise addition by pipette, (b) syringe pump system, (c) syringe pump controlled by peroxide-sensitive electrode, and *in situ*: (d) H_2O_2 generation by an oxidase, (e) generation by illuminated flavins and (f) electrochemical H_2O_2 generation by a gas diffusion electrode.

Table 4 Comparison of different methods to supply UPOs with hydrogen peroxide (H₂O₂)

Method	Equipment	Advantage	Disadvantage	Ref.
<i>Ex situ</i> supply	Pipette	Robust and fast dosing; volume steps easily adjustable; easy handling	High local H ₂ O ₂ concentration at the point of entry/ in-jection; limited maximum H ₂ O ₂ amounts depending on the total volume	(Ullrich <i>et al.</i> , 2008; Ullrich and Hofrichter, 2005; Ullrich <i>et al.</i> , 2004)
<i>Ex situ</i> supply	(Syringe) pump	Accurate fine dosing, continuous dosing	High local H ₂ O ₂ conc. at the point of entry; limited maximum H ₂ O ₂ amounts depending on the total volume	(Aranda <i>et al.</i> , 2010; Karich <i>et al.</i> , 2017)
Sensor controlled <i>ex situ</i> supply	H ₂ O ₂ -sensor controlled pump (H ₂ O ₂ -stat)	Optimal H ₂ O ₂ -dosage for each reaction; technically applicable (at large scale)	Limited availability and high price of H ₂ O ₂ -sensors	(van Deurzen <i>et al.</i> , 1997b)
Photochemical in situ generation	Solely photochemical or in combination with enzymatic reactions (flavins)	Accurate fine dosing; inexpensive (if once established)	Limited availability of photochemical equipment; sluggish reaction kinetics; accumulation of by-products; O ₂ -limitation	(Perez <i>et al.</i> , 2009; Willot <i>et al.</i> , 2019; Zhang <i>et al.</i> , 2017, 2018)
Electrochemical in situ generation	Gas diffusion electrode	Accurate fine dosing; almost perfect distribution of H ₂ O ₂	Limited availability of electrochemical equipment; tricky handling	(Getrey <i>et al.</i> , 2014; Horst <i>et al.</i> , 2016; Krieg <i>et al.</i> , 2011)
Enzymatic in situ generation I	Glucose oxidase	Accurate fine dosing; inexpensive; easy handling and availability	Poor atom-efficiency, accumulation of by-products (glucono-lactone); O ₂ -limitation	(Bankar <i>et al.</i> , 2009; Pereira <i>et al.</i> , 2015)
Enzymatic in situ generation –cascade reaction II	Different oxidoreductases (enzyme cocktail)	Accurate fine dosing, simple handling; co-solvent acts as substrate for the cascade; final by-product CO ₂	Non-commercial enzymes; requires NAD ⁺ and additional oxidases; O ₂ -limitation	(Ni <i>et al.</i> , 2016; Pesic <i>et al.</i> , 2018)
Enzymatic in situ generation –cascade reaction III	Different oxidases (e.g., aryl alcohol oxidase, galactose oxidase)	Accurate fine dosing; simple handling, UPO utilizes H ₂ O ₂ produced by oxidases, no by-products/waste	Non-commercial enzymes; requires additional oxidases; O ₂ -limitation	(Karich <i>et al.</i> , 2018)

advantages, e.g., inexpensive reaction design, no need of additional co-substrates, no by-products, optimal fine dosing and completeness of oxidation.

Other approaches have combined more than two peroxide-supplying enzymes and UPO, such as alcohol oxidase from *P. pastoris* (EC 1.1.3.13), formaldehyde dismutase from *Pseudomonas putida* (E.C.1.2.99.4), formate dehydrogenase from *Candida boidinii* (EC 1.2.1.2) and 3-hydroxybenzoate 6-hydroxylase from *Rhodococcus jostii* (EC.1.14.13.24). This advanced system generates three equivalents of H₂O₂ from one methanol molecule and was successfully tested in the UPO-catalyzed conversion of ethylbenzene into enantiopure (*R*)-1-phenylethanol (Fernández-Fueyo *et al.*, 2016; Ni *et al.*, 2016; Pesic *et al.*, 2018). This setup will be especially smart, if methanol is the co-solvent to enhance ethylbenzene solubility (Ni *et al.*, 2016).

Besides the enzymatic in situ generation of peroxide, two technical approaches using electrochemical or photochemical equipment have successfully been tested in oxyfunctionalization trails with AaeUPO (Fernández-Fueyo *et al.*, 2016; Horst *et al.*, 2016; Krieg *et al.*, 2011; Zhang *et al.*, 2017, 2018). The photochemical setup allowed the direct control of H₂O₂ generation by light intensity but required isolated flavins and reduced organic compounds for peroxide generation (Zhang *et al.*, 2018, 2017). Electro-enzymatic hydroxylation of ethylbenzene with rAaeUPO used electrodes to generate H₂O₂ by reduction of oxygen and facilitated total turnover numbers of up to 400,000 (Horst *et al.*, 2016). The use of electrodes to fuel UPOs may be particularly attractive in pharmaceutical synthesis and red biotechnology, since it fully prevents the formation of undesired by-products during peroxide generation.

Immobilization

One strategy to decrease the costs for enzymes is to improve their recyclability (Gao *et al.*, 2019). Immobilization is the mostly used method to achieve this. In the case of UPOs, encapsulation of the protein (AaeUPO, MroUPO) in polymeric beads (“enzyme pearls”) was demonstrated. The bead matrix consisted of cross-linked polyvinyl acetate and/or polyethylene glycol forming a three-dimensional gel network where the enzyme molecules were entrapped (Poraj-Kobielska *et al.*, 2015). A second approach reported by the same authors used hollow fiber modules that retained the UPO protein by a defined membrane system. Both protein fixation methods, however, do not represent “true” immobilization techniques, since the UPO protein was not covalently bound to the matrix. In consequence leaching effects may adversely affect enzyme performance.

Covalent immobilization of CPO using various chemical and enzymatic coupling methods has been intensely studied over several decades. In all cases, however, immobilization was accompanied by partial enzyme inactivation (Gao *et al.*, 2019; Kadima and Pickard, 1990) and there have been only few studies that reported a comparable performance of immobilized CPO compared to free enzyme (Petri *et al.*, 2004). Not much has been reported on the covalent immobilization of UPOs. Only very recently, it was

Fig. 9 Stepwise hydroxylation of sp^3 -hybridized carbons catalyzed by UPOs in dependence of abstractable hydrogen (C-H). UPOs oxidize the primary carbon of a methyl group (a) via corresponding primary alcohol and aldehyde derivatives into a carboxylic acid. Secondary carbon (b) is oxidized via a secondary alcohol into a ketone, and tertiary carbon (c) is hydroxylated to a tertiary alcohol. Aldehydes, ketones and carboxylic acids are shown in equilibrium with their corresponding hydrates.

demonstrated that UPO mutants (*rAaeUPO*) can be efficiently immobilized by the DUCI-technique (directed unique-point covalent immobilization). This structure-guided method is based on the engineering of Cys⁺-mutants, the additional cysteine of which, at the protein surface, selectively interacts with the immobilization-carrier via a single disulfide bridge that may even ensure a controlled orientation of the enzyme (Molina-Espeja *et al.*, 2019). Such UPO mutants and the DUCI-technique could be the method of choice when industrial applications of UPOs in the pharmaceutical or fine chemical sector will be envisaged.

Reactions Catalyzed by UPOs

UPOs catalyze diverse oxyfunctionalization reactions including hydroxylations of sp^3 -carbon and epoxidations of sp^2 -carbon, some of which may undergo following reactions such as dealkylation or re-aromatization. Organic heteroatoms such as sulfur and nitrogen are subject of oxygen transfers as well, and inorganic halides are peroxygenated to hypohalites, which in turn can halogenate other molecules. This subarticle will give a concise overview on some of these reactions that are also summarized in Table 5.

Carbon Oxygenations

Only some UPOs (including CPO) have been demonstrated to catalyze a huge number of oxygenations of carbon atoms, which is reflected by the number of original papers (compare Tables 2–5) and review articles that have been published in the last two decades (Bormann *et al.*, 2015; Dembitsky, 2003; Hofrichter and Ullrich, 2006, 2011, 2014; Hofrichter *et al.*, 2015, 2020; Kiebiest *et al.*, 2019; Manoj and Hager, 2008; Ullrich and Hofrichter, 2007; Wang *et al.*, 2017). Here, we focus on hydroxylations of sp^3 -hybridized carbons as well as on epoxidations of sp^2 -hybridized carbons. This includes the selective conversion of pharmaceuticals and the rather unspecific conversion of environmental pollutants. Furthermore, we discuss some peroxygenations of some naturally and physiologically important substances.

Hydroxylations (sp^3)

In general, the UPO-mediated stepwise oxidation of carbon starts with the insertion of an oxygen leading to the corresponding alcohol. In the case of primary and secondary alcohols, a further hydroxylation may take place at the same carbon resulting in the formation of the corresponding aldehydes or ketones (The second peroxygenation of a carbon already bearing an alcohol functionality is also known as over-oxidation (Campestrini *et al.*, 2004; Holtmann *et al.*, 2014)), which are in equilibrium with their hydrates (*gem*-diols). Finally, aldehydes can undergo a third peroxygenation to the corresponding carboxylic acids (Figs. 9 and 10). These reactions strongly depend on the reaction conditions, among which the ratio between substrate and peroxide is most important. For example, Peter *et al.* (2011)

Structure	Compounds	Primary products	Secondary products	Tertiary products	UPO (Ref.)

Note, both carbon types (*sp*³, *sp*²) are present in the same molecules. * Indicates unstable epoxide intermediates rearranging via re-aromatization and formation of phenolic products.

The peroxygenation of cyclic alkanes by AaeUPO was shown for C5-C8 rings yielding mainly the corresponding cycloalkanols (Peter et al., 2011). With the intention to prepare cyclohexanol and cyclohexanone, four UPOs (rHinUPO, AaeUPO, MroUPO, rCciUPO) were tested, among which MroUPO productively utilized 87% of the added H₂O₂ to form the envisaged products with high yield (Peter et al., 2014). Terminal and secondary benzylic carbons (R-CH₃, R-CH₂-alkyl), which are particularly favored targets because of the activating effects of the phenyl moiety, were oxidized either to benzyl alcohol, benzaldehyde and benzoic acid derivatives or to the corresponding (R)-1-phenyl alkanols and to smaller amounts of respective ketones (Kinne et al., 2010; Fernández-Fueyo et al., 2016; Figs. 10 and 11). The conversion of linear and branched alkanes proceeded with some regioselectivity typically yielding 2- and 3-alkanols and again small amounts of ketones. With regard to fatty acids, these positions correspond to ω -1 and ω -2, respectively. Gutiérrez et al. (2011) detected traces of other hydroxylation products at ω , ω -3 and ω -5 positions in stopped-flow experiments with 3,3-dimethylbutanoic acid as substrate. Just lately, Olmedo et al. (2017) demonstrated that MroUPO catalyzes the shortening of fatty acids. This interesting reaction sequence requires the incipient peroxygenation of the C- α position, which is further oxidized to a gem-diol derivative that is in equilibrium with the α -keto fatty acid. A final spontaneous oxidation that may be forced by peroxide yields the decarboxylated fatty acid. By analogy with well-known β -oxidation, this route could be assigned as the α -oxidation of fatty acids. Similar consecutive peroxygenations and spontaneous oxidation were proposed for the side-chain removal from corticosteroids (Ullrich et al., 2018).

The scission of ethers (O-dealkylation) is another reaction that is initiated by the peroxygenation of a carbon, in this case of the ether bond's adjacent methylene (R-O-CH₂-R') or methyl (R-O-CH₃) groups. Kinne et al. (2009b) first demonstrated this reaction type using AaeUPO and diverse ether substrates including linear, branched and cyclic compounds (e.g., diethyl ether, diisopropyl ether, tetrahydrofuran). Upon hydroxylation, an unstable hemiacetal is formed (e.g., R-O-CH₂-OH-R') that spontaneously cleaves into an alcohol (R-OH) and an aldehyde (O=CH₂-R'), in which the alcohol bears the oxygen of the original ether (the carbonyl is the result of water addition). Analogously UPOs perform N-dealkylations via hemiaminal intermediates. Among others, this was demonstrated for some pharmaceuticals and alkyl anilines using AaeUPO and CPO, respectively (compare Table 5) (Corbett et al., 1979, 1978; Corbett and Chipko, 1979; Kinne et al., 2010; Poraj-Kobielska et al., 2011). An ester scission as special case of O-dealkylation was exclusively reported for the reaction of CraUPO with the antiviral drug osaltamivir (Poraj-Kobielska et al., 2011).

Epoxidations (*sp*²)

Benzene represents the simplest arene molecule and may serve as an example for the conversion of aromatic substrates by UPOs. Only AaeUPO was found to peroxygenate this inactivated *sp*² system in substantial amounts (Karich et al., 2013). The major products observed were phenol (hydroxybenzene) and dihydroxybenzenes (catechol, hydroquinone) along with smaller amounts trihydroxybenzenes. UPOs of family II (AaeUPO and CraUPO to some extent) seemingly favor the reaction with the unsubstituted monoarene ring, while members of family I like MroUPO hardly oxidize benzene. As assumed for all "aromatic hydroxylations", the reaction proceeds via an initial epoxidation to the corresponding arene oxide (epoxyarene), which is in equilibrium with the corresponding oxepine (Karich et al., 2013; Fig. 12). Driven by the force of re-aromatization, an isomerization to the corresponding phenol follows (Karich et al., 2013; Kluge et al., 2009). This type of oxyfunctionalization of aromatic carbons was shown for various substituted benzenes, naphthalene and polycyclic aromatic hydrocarbons (PAH) (Aranda et al., 2010; Karich et al., 2017; Kluge et al., 2009; Kinne et al., 2010, 2009a).

The peroxygenation of alkenes (aliphatic, cyclic and benzylic derivatives) analogously results in the formation of epoxide products. However, due to a lacking driving force, i.e., re-aromatization, the rearrangement of these epoxides is not promoted and they remain relatively stable (Lin et al., 2011; Peter, 2013). Epoxidation of aliphatic *sp*² carbons was proven to be catalyzed by all

known UPOs with a high diversity of substrates, e.g., aliphatic alkenes, unsaturated fatty acids and cyclic alkenes including complex terpenes and steroids (Aranda *et al.*, 2018a, 2019; Kiebitz *et al.*, 2017; Peter, 2013; Peter *et al.*, 2013; Figs. 11 and 12).

Alkynes (sp^1)

The conversion of 1-octyne and 1-hexyne was merely shown for AaeUPO and led to the formation of 1-octyn-3-ol and 1-hexyn-3-ol, respectively, but the triple bond as such was not attacked. The reaction was inefficient and incomplete, which points to enzyme inactivation as in the case of P450s. Non-terminal alkynes, such as 2-hexyne or 3-hexyne, were not subject of conversion by AaeUPO (Peter, 2013). Probably trace amounts of highly reactive carbonyl alkenes are formed, which in turn react with the prosthetic heme of UPOs under formation of inactivating *N*-alkyls (Dexter and Hager, 1995; Peter, 2013). Similar findings were reported for the reaction of CPO with alkynes (Dembitsky, 2003).

Limitations

Limitations concerning the peroxygenation reactions of UPOs can be briefly summarized as follows: (1) steric hindrance, (2) the absence of abstractable hydrogen at the attacked carbon and (3) C–H bond dissociation energy (BDE). Unless the latter constraint, the other limitations strongly depend on the particular UPO and its structure.

Steric constraints that limit the substrate spectrum of UPOs are not surprising, since the oxygen insertion requires the direct contact of the substrate with the ferryl oxygen of the activated heme (Cpd-I). In the case of long UPOs and PAH, the current limit is given by perylene (5-ring molecule, $C_{20}H_{12}$) that was neither oxidized by AaeUPO nor by CraUPO (Aranda *et al.*, 2010). Also, the large ring system of cyclodecane ($C_{10}H_{20}$) was not open to attack by AaeUPO (Peter, 2013). On the other hand, rather bulky steroids were converted depending on the substitution pattern of the sterane body. For example, cholesterol and campesterol were transformed with appreciable conversion rates (10%–100%) whereas only 2% of stigmasterol was oxidized by rCciUPO, AaeUPO and MroUPO (Babot *et al.*, 2015). 2,2,3,3-Tetramethylbutane may serve as an example of molecules that are not attacked by UPOs due to the lacking of abstractable hydrogens. The molecule contains six terminal carbons that cannot be oxidized because of the high bond energies, and the central two carbons are lacking abstractable hydrogens (Peter, 2013). Eventually, methane with its exceptional high C–H BDE of $105 \text{ kcal mol}^{-1}$ was not converted by AaeUPO (Peter, 2013), which is in accordance with the BDE versus log *k* plot for AaeUPO Cpd-I (Wang *et al.*, 2012).

Oxygenation of Heteroatoms

Besides the oxygenation of C-atoms, UPOs were shown to peroxygenate organic heteroatoms, i.e., nitrogen and sulfur. UPOs will favor *N*-dealkylation over *N*-oxidation, if the nitrogen is substituted with aliphatic residues as discussed under 4.1. Otherwise, when the nitrogen is of aromatic or benzylic nature – as in pyridine or *N*-alkyl anilines – *N*-oxidation can be observed (Fig. 13 (Corbett *et al.*, 1978; Ullrich *et al.*, 2008)). Pyridine and its derivatives are strongly inactivated substrates. Thus, it was not surprising that the product yields of pyridine *N*-oxides were poor in respective conversions with AaeUPO (Ullrich *et al.*, 2008). Interestingly, phenolic products were not observed. Maybe the heterocyclic nitrogen tends to coordinate towards the heme iron at the active site so that UPO attack favors it over carbons. *N*-oxidation of anilines was intensely studied with CPO (Corbett *et al.*, 1978; Corbett and Chipko, 1979; Corbett *et al.*, 1979), and was also observed in reactions of AaeUPO (Kinne, 2010). However, when comparing the oxidation of aniline and *N*-methyl-4-chloroaniline catalyzed by AaeUPO and CPO, respectively, it is not clear why no *N*-dealkylation product was found in the latter reaction (Kinne, 2010; Corbett and Chipko, 1979).

AaeUPO and CPO catalyze sulfoxidations and that of aryl-alkyl sulfides was studied in more detail, because of its intriguing enantioselectivity (Bassanini *et al.*, 2017; Colonna *et al.*, 1992; Horn, 2009; Kobayashi *et al.*, 1987). In all cases, the absolute configuration of the sulfoxides was (R) (Except in one case, where the absolute configuration was reverse due to a change in the substituent priority according to the sequence rules (Bassanini *et al.*, 2017)) and the enantiomeric excess ranged from 5% to >99% (Fig. 14). Whereas the product yield of the reaction was mostly higher with AaeUPO, the ee-values for CPO were in the same order of magnitude (Bassanini *et al.*, 2017). Besides aryl-alkyl sulfides, sulfoxidations were also observed for other substrates such as the pharmaceutical (omeprazole) and the petroleum constituent dibenzothiophene (Aranda *et al.*, 2009; Poraj-Kobielska *et al.*, 2011).

Halogenations

Chlorination reactions were first described for CPO in the early 1960s (Hager *et al.*, 1966). In the following decades, the catalytic mechanism was intensely studied (Libby *et al.*, 1982; Yamada *et al.*, 1985). CPO catalyzes a large number of chlorinations on various substrates including phenols, PAH, aromatic acids, unsaturated fatty acids and dienes (Vázquez-Duhalt *et al.*, 2001). In addition to chloride, bromide was accepted as halide source resulting in the bromination of diverse compounds (Yamada *et al.*, 1985). The mostly acknowledged reaction mechanism includes the formation of reactive hypohalites, which subsequently attack preferably sp²-hybridized carbons (Dembitsky, 2003). Hence, a well-established assay for CPO activity measurement involves monochlorodimedone (MCD) that is halogenated via hypohalite intermediates produced by the enzyme and by means of H₂O₂. The corresponding dihalogenated dimedone does not allow keto-enol tautomerism anymore, which is essential for MCD's specific UV-vis spectrum, and thus, leads to a decrease in absorbance at 290 nm (Hager *et al.*, 1966; Libby *et al.*, 1982). Unfortunately, this assay can give false positive results, caused by halogen-independent oxidation of MCD to so far unknown products (Wagner *et al.*, 2008). In addition to MCD, the halogenating activity was tested with phenol in presence of KCl or KBr. With that set-up, CPO showed high chlorinating activities yielding 4- and 2-chlorophenol as well as dichlorophenols as products. In contrast, AaeUPO,

Fig. 15 Indirect bromination of phenol by CPO and *Aae*UPO resulting in mixtures of 2-bromophenol and 4-bromophenol. In the first step, bromide (Br^-) is enzymatically peroxylated to hypobromite (BrO^-) and in the second step, hypobromite attacks the aromatic ring at the *ortho*- and *para*-positions.

*Cra*UPO and *Cve*UPO chlorinated phenol poorly and merely traces of 2-chlorophenol were detected. When bromide was provided, however, all four UPOs converted phenol into 2-bromo- and 4-bromophenol in the ratio of 1:4 (Fig. 15; Anh, 2008; Anh *et al.*, 2007; Ullrich and Hofrichter, 2005). Surprisingly, *Mro*UPO neither chlorinated nor brominated phenol (Gröbe *et al.*, 2011). There is obviously a high variation in the halogenation capabilities among UPOs. The molecular factors affecting the ability of UPOs to perform halogenation reactions are not well understood yet.

Conclusions and Outlook

Without doubt, UPOs belong to the most versatile enzymatic oxyfunctionalization tools and are becoming more and more relevant with respect to synthetic applications. On the one hand, their substrate spectrum is extremely broad, while on the other hand, the reactions catalyzed can be highly specific with regard to regio- and enantioselectivity. UPOs are rather stable biocatalysts, and if the peroxide is gently delivered, they will accomplish high process stability and reaction performance. These features define two major fields of (future) applications. The first one is related to the oxidation of low-value bulk chemicals and detoxification of a broad range of ecotoxicologically relevant substances, including drug residues found in municipal or pharmaceutical wastewater. For the application of UPOs in this field, the production costs of the enzymes to be applied must be as cheap as possible and they must be re-cyclable. In any case, it is recommended to optimize the envisaged reactions and the set-up regarding the supply and consumption of peroxide. The second field of application should focus on high-value products, for example, enantiopure pharmaceuticals, drug intermediates or fragrances. For this type of application, it will be important to find the UPO of choice that will catalyze the intended reaction regio- and/or enantioselectively with appreciable yields. So far, about merely twenty UPOs have been prepared and characterized, but in fact more than 4300 UPO encoding genes were identified in fungal genomes, indicating an amazing scientific and application potential for the future. A large natural pool of UPOs is available and simply waits for its exploitation. The main bottleneck that will have to be overcome is the production of UPOs at the kg and tons level. Only a global player such as Novozymes A/S may have the economic power and know-how to implement this at an appropriate scale. Besides the naturally “available” UPOs, strong potential also lies in the engineering UPOs, e.g., with regard to substrate spectrum, process stability, heterologous expression and directed evolution. Last but not least, it has to be mentioned in a UPO review again: Though we already know a lot about UPOs with regard to structure, genes, catalyzed reactions and application potential – our knowledge on their natural functions and roles in fungal physiology is rather scarce. They could be “an extracellular liver” of fungi, which helps them, as immotile organisms, to eliminate all kinds of toxins in their microenvironment or they may be part of the biochemical machinery of pathogenic fungi, which attack plant, fungal or animal hosts. Therefore, future UPO research will have to focus on more basic and ecological aspects of these fascinating enzymes, which surely will also have positive spin-off effects for applied research.

Introduction

For long, the enzymatic degradation of polysaccharides was thought to be exclusively catalyzed by the concerted action of multiple hydrolytic enzymes such as endo- and exo-acting cellulases. Many fungi, including the archetype cellulolytic ascomycete *Trichoderma reesei* (Gritzali and Brown, 1979), indeed produce a wide range of cellulases that find multiple industrial applications. Among these are cellulases belonging to the glycoside hydrolase family 7 (GH7) in the CAZy database (Lombard *et al.*, 2014), which are among the most powerful cellulolytic enzymes known (Teeri *et al.*, 1998) and which occur almost exclusively in fungi (Payne *et al.*, 2015).

Following an observation, in 1974, that oxygen promotes cellulose degradation by fungal secretomes (Eriksson *et al.*, 1974), which remained somewhat overlooked for decades, it was discovered in 2010 that both fungi and bacteria produce copper-dependent redox enzymes that contribute to polysaccharide conversion (Phillips *et al.*, 2011; Quinlan *et al.*, 2011; Vaaje-Kolstad *et al.*, 2010). These enzymes, currently known as lytic polysaccharide monooxygenases (LPMOs), are unique in that they have the ability to cleave glycoside bonds in a crystalline context. In other words, their action does not depend on expelling an individual polysaccharide chain from a cellulose or chitin crystal, as is the case for classical hydrolytic enzymes. In that sense, LPMOs are truly interfacial enzymes, acting at the interface between the surface of an insoluble substrate (cellulose, chitin, plant cell walls) and the surrounding aqueous medium.

Next to the discovery of LPMOs, this chapter describes multiple aspects of these fascinating enzymes. We describe the occurrence of LPMO-encoding genes and show that LPMOs are abundantly encoded in many fungal genomes, which indicates importance and possible functional versatility. Furthermore, we describe the LPMO reaction and discuss that, since this reaction depends on reducing equivalents and an oxygen source (O_2 or H_2O_2), the reaction is difficult to study and is affected by the presence of other redox enzymes. Finally, we discuss the positive impact of LPMOs on the efficiency of enzyme cocktails for processing of plant biomass, which has led to industrial application of these enzymes.

The Discovery of LPMOs and Basic Structural and Functional Information

The discovery of LPMOs was a result of studies aiming at understanding depolymerization of natural polysaccharides including cellulose and chitin (Harris *et al.*, 2010; Moser *et al.*, 2008; Vaaje-Kolstad *et al.*, 2005). The occurrence, structure and catalytic activity of proteins that later turned out to be LPMOs were studied in parallel for fungal and bacterial proteins. The first such protein described in fungal secretomes was initially referred to as cellulose-induced protein (Raguz *et al.*, 1992) or endoglucanase, due to the observation of a weak endoglucanase-like activity (Saloheimo *et al.*, 1997). The first such proteins in bacteria were proteins referred to as chitin-binding proteins (Schnellmann *et al.*, 1994). Based on these initial findings, these fungal and bacterial proteins were initially classified into the Glycoside Hydrolase (GH) family 61 (GH61) and Carbohydrate-Binding Module (CBM) family 33 (CBM33), respectively, in the Carbohydrate-Active enZymes (CAZy) database (Lombard *et al.*, 2014).

A major breakthrough came in 2005, when Vaaje-Kolstad *et al.* showed that a CBM33 protein could dramatically boost the conversion of chitin by chitinases (Vaaje-Kolstad *et al.*, 2005). It took until 2010 to discover that both CBM33s and GH61s, in fact, catalyze oxidative cleavage of polysaccharides (Phillips *et al.*, 2011; Quinlan *et al.*, 2011; Vaaje-Kolstad *et al.*, 2010). These enzymes are now collectively referred to as LPMOs and have been reclassified in the CAZy database into the Auxiliary Activity families 9 (AA9; for GH61) and 10 (AA10; for CBM33) LPMOs. The potential that LPMOs may speed up depolymerization of recalcitrant polysaccharides by an order of magnitude (Vaaje-Kolstad *et al.*, 2010) has placed LPMOs in the spotlight of research on enzymatic conversion of biomass (Chylenski *et al.*, 2019; Tandrup *et al.*, 2018).

LPMOs are secreted copper-dependent redox enzymes that share a common immunoglobulin-like β -sheet core and a distinct active site with the copper ion being coordinated by a so-called His-brace (Ciano *et al.*, 2018; Quinlan *et al.*, 2011; Vaaje-Kolstad *et al.*, 2017). The His-brace is composed of the N-terminal histidine, contributing two nitrogen ligands, one from the N-terminal amino group and one from the imidazole side chain, and another fully conserved histidine, contributing a third nitrogen ligand with its imidazole side chain. In fungal LPMOs (and LPMO-like proteins; see below), the N-terminal imidazole is methylated (Filiatrault-Chastel *et al.*, 2019; Labourel *et al.*, 2020; Lo Leggio *et al.*, 2015; Navarro *et al.*, 2014; Quinlan *et al.*, 2011), whereas the post-translational modification has not been observed in bacterial LPMOs. In between the segments forming the sheet-like core structure, LPMOs contain several insertions/loops with varying lengths that shape the substrate-binding surface around the active site. Several of these loops have been annotated (such as the “L2 loop”) and are also called active site segments (Borisova *et al.*, 2015; Laurent *et al.*, 2019; Wu *et al.*, 2013).

Based on sequence variation, LPMOs are, to date, classified into seven CAZy families: AA9–11 and AA13–16 (Levasseur *et al.*, 2013). Of 717 scrutinized fungal genomes, 531 (74%) encode one or multiple genes encoding AA9, AA11, AA13, AA14 and/or AA16 LPMOs (see below; **Table 1**). Although the structural basis of LPMO substrate specificity remains largely unknown, LPMOs show huge variation in the length and composition of the loop structures that connect their core segments, leading to variation in the catalytic surface, which likely enables different LPMOs to interact with substrates with different structures (**Fig. 1**). As of today, fungal LPMOs have been found to be able to cleave a broad range of natural polysaccharides, including cellulose, hemicelluloses, chitin and starch. The most abundant fungal LPMOs are the AA9s, known to target cellulose, β -glucans such as xyloglucan and mixed-linkage glucan, glucomannan, xylan and/or oligosaccharides (Frommhagen *et al.*, 2018). Other fungal LPMOs occur in family AA11, targeting chitin (Hemsworth *et al.*, 2014), family AA13, targeting starch (Vu *et al.*, 2019), family AA14, targeting cellulose-bound xylan (Couturier *et al.*, 2018), and family AA16, targeting cellulose (Filiatrault-Chastel *et al.*, 2019).

LPMOs act by hydroxylating one of the carbons in the scissile glycosidic bond. In other words, an oxygen atom is introduced into a C–H bond, hence the name monooxygenase. This hydroxylation destabilizes the glycosidic bond, which spontaneously breaks (Phillips *et al.*, 2011). Cellulose-active LPMOs may act exclusively at the C-1 or C-4 position, or produce a mixture of C1- and C4-oxidized products (Isaksen *et al.*, 2014; Phillips *et al.*, 2011; Quinlan *et al.*, 2011; Vu *et al.*, 2014). Initially, it was thought that LPMOs carry out a monooxygenase reaction, which implies that they use molecular oxygen and two externally delivered electrons to oxidize the substrate (**Fig. 1(E)**) (Quinlan *et al.*, 2011; Vaaje-Kolstad *et al.*, 2010; Walton and Davies, 2016). In the absence of substrate, LPMOs supplied with reductant and O_2 will produce H_2O_2 (Isaksen *et al.*, 2014; Kittl *et al.*, 2012), and this oxidase activity shows that LPMOs indeed can reduce molecular oxygen. More recently, it has been shown that LPMOs can also, and much more efficiently, catalyze a peroxygenase reaction, meaning that the enzyme employs H_2O_2 rather than O_2 (**Fig. 1(E)**) (Bissaro *et al.*, 2017, 2020; Filandr *et al.*, 2020; Hangasky *et al.*, 2018; Jones *et al.*, 2020; Kuusk *et al.*, 2018). In this case, only catalytic, rather than stoichiometric, amounts of reductant are needed to drive the reaction. One open question in the field is whether O_2 -driven LPMO-catalyzed cleavage of glycosidic bonds indeed occurs, or whether apparent monooxygenase reactions are in fact limited by *in situ* generation of H_2O_2 , which would then be the “true” co-substrate (Bissaro *et al.*, 2017, 2018; Wang *et al.*, 2019).

Hydrogen peroxide plays a central role in fungal metabolism, which is in part reflected by the secretomes of fungi being rich in oxidoreductases. These oxidoreductases potentially interact with LPMOs either via direct electron transfer (Tan *et al.*, 2015) or through intricate reaction networks connected by reactive oxygen species (Bissaro *et al.*, 2018; Frommhagen *et al.*, 2018). In addition, fungi secrete a broad variety of redox-active compounds, which may act as reducing agent of LPMOs (Frommhagen *et al.*, 2016, 2018; Kracher *et al.*, 2016) and interact with reactive oxygen species. This is detailed further below.

Occurrence of LPMOs and LPMO-Like Proteins in Fungi

LPMOs are abundant in the fungal kingdom, in particular in Dikarya, but are also found in early diverging fungi. In dikaryotic fungi, we find at least one copy of LPMOs belonging to the families AA9, AA11, AA13, AA14 or AA16 in 84% of Ascomycetes and 68% of Basidiomycetes (**Table 1**).

Among these, the chitin-active AA11 LPMOs are the most widespread as they occur in Dikarya and most early diverging (so-called basal) fungal lineages. Genes encoding AA11s are even found in the phylum Cryptomycota, comprising the most basal unicellular fungal species, indicating an ancient origin of these enzymes. Considering that the fungal cell wall contains chitin, it is plausible that AA11 LPMOs are involved in cell wall remodeling and growth, as has been shown recently for a membrane-bound AA11 from *Neurospora crassa* (Gonçalves *et al.*, 2019). On the other hand, the AA11 LPMOs found in entomopathogenic fungi (e.g., *Cordyceps* and *Ophiocordyceps* sp. among ascomycetes and members of the fungal order Entomophthorales, such as *Conidiobolus coronatus*, among zoopagomycetes) are potentially used to degrade the chitinous exoskeleton of insects. In two fungal species belonging to the phylum Zoopagomycota, the number of AA11 genes exceeds 20 copies in a single genome, as it is the case in the soil inhabiting fungus *Basidiobolus meristosporus* CBS 931.73 (43 copies (Mondo *et al.*, 2017)) and the entomopathogenic fungus *C. coronatus* NRRL 28638 (23 copies (Chang *et al.*, 2015)). In Dikarya, the highest number of AA11 genes is found in the ectomycorrhizal fungus *Choiromyces venosus* 120613-1 (pig truffle), which displays 14 AA11 genes (Murat *et al.*, 2018), some of which are likely to have a role in fungal cell wall remodeling.

The family AA9 is the second most widespread LPMO family in fungi. AA9 LPMOs are predominantly found in Dikarya, where 57.5% of Basidiomycetes and 76.6% of Ascomycetes have one or more AA9 genes (**Fig. 2**). A large expansion of AA9 genes has occurred in Dikarya, with an average of 12 genes in both Ascomycota and Basidiomycota. While some species carry no or only a single copy of an AA9 gene, some species have evolved to carry over 50 AA9 genes. As an example, the ascomycete plant pathogen *Verticillium longisporum* has 53 AA9 genes (Fogelqvist *et al.*, 2018), and the basidiomycete plant pathogen *Rhizoctonia solani* has 55 AA9 genes (Wibberg *et al.*, 2013). Considering that AA9 LPMOs have been shown to target a broad variety of plant polysaccharides (Frommhagen *et al.*, 2018), the complexity of plant cell walls (Lampugnani *et al.*, 2018; Somerville *et al.*, 2004) may explain the multiplicity of AA9 LPMOs in Dikarya, which predominantly comprise plant biomass degraders, plant symbionts and plant pathogens. Detailed biochemical characterization of multiple AA9 LPMOs belonging to the same organisms, such as the ascomycetes *Malbranchea cinnamomea* (Hüttner *et al.*, 2019), *Myceliophthora thermophila* (Frommhagen *et al.*, 2016), *N. crassa* (Petrović *et al.*, 2019) and *Podospora anserina* (Bennati-Granier *et al.*, 2015), indicate that AA9 LPMOs may have evolved to functionally adapt to distinct co-polymeric substructures in the plant biomass. In addition, LPMOs have been shown to react differently with a

Table 1 *The occurrence of LPMOs and LPMO-like proteins in fungi.* The table shows the number of analysed genomes within each major fungal division, the number of species containing genes encoding LPMOs (individual AA families or all AA families combined) or LPMO-like proteins (X325), and the number of those genes (range and average) for the individual genomes in each phylum. The data were generated by searching with HMM-profiles of characterized LPMOs against the UniProt Reference Proteomes database, containing 717 fungal reference proteomes. For AA9 LPMOs, HMM profiles were generated based on the sequences of 37 functionally characterized AA9 LPMOs. For the other LPMO families and LPMO-like proteins, of which only a handful of proteins have been characterized so far, HMM profiles were generated based on the sequences of 50 proteins (LPMO/LPMO-like domains only) sharing 40%–100% sequence identity with the characterized one(s)

range of electron donors (Frommhagen *et al.*, 2016; Kracher *et al.*, 2016; Petrović *et al.*, 2019), indicating a possible adaptation to different types of redox partners, the occurrence of which may vary in distinct ecological niches.

The cellulose-active AA16 LPMOs occur exclusively in Dikarya, whereas the xylan-active AA14 LPMOs occur predominantly in Dikarya, primarily in the genomes of filamentous ascomycete fungi and basidiomycetous wood decay fungi. The gene copy number of AA14s and AA16s (on average, 1–2 per genome) is considerably lower than that of AA9s (on average, 12 per genome), which may reflect low diversity in substrate specificity among AA14s and AA16s. Accordingly, AA14 LPMOs have been shown to target recalcitrant xylan that is bound to cellulose, representing a specific substructure in the plant cell wall (Couturier *et al.*, 2018). Available data for the only AA16 characterized so far indicate activity on cellulose (Filiatrault-Chastel *et al.*, 2019). Notably, unlike the other LPMO families, AA14s are more widespread among Basidiomycetes than among Ascomycetes, with 61% versus 24% of the sequenced species carrying AA14 genes, respectively. Considering that the only fungi able to completely degrade all wood components are found in Basidiomycota (i.e., white-rot fungi), one might speculate that AA14s contribute to this ability. In addition to dikaryotic fungi, only two species from the early diverging fungi have been found to carry AA14 genes so far, the chytridiomycete *Spizellomyces punctatus* and the blastocladiomycete *Catenaria anguillulae*, with three and one genes, respectively (Mondo *et al.*, 2017; Russ *et al.*, 2016). The similarity of these genes to dikaryotic AA14s and the absence of these genes in the vast majority of early diverging fungal genomes indicate that these genes likely have been acquired by horizontal gene transfer events. However, more extensive sampling of the genomes of early diverging fungi is necessary before such conclusions can be drawn.

In addition to the LPMO families described above, the genomes of roughly one third of the sequenced Ascomycetes carry one to three AA13 LPMOs, which, based on current knowledge, act on starch (Table 1). The reason for the low copy number of AA13s in the genomes could be that starch is less recalcitrant and less complex than plant cell wall polysaccharides. AA13 LPMOs seem to be specific to Ascomycetes as, so far, only one basidiomycete species, *Psilocybe cyanescens*, has been found to carry AA13 genes (Reynolds *et al.*, 2018). The absence of AA13s in 166 of the 167 basidiomycete proteomes available in the UniProt Reference Proteomes database suggests that *P. cyanescens* obtained the AA13 genes by horizontal gene transfer.

In addition to catalytically active LPMOs in the CAZy AA families, LPMO-like proteins have recently been described in biomass decayers (Labourel *et al.*, 2020) and the human pathogen *Cryptococcus neoformans* (García-Santamarina *et al.*, 2020). Although these LPMO-like proteins from the X325 family share a similar fold with LPMOs and contain the characteristic copper-binding histidine brace (Labourel *et al.*, 2020), no apparent catalytic activity towards polysaccharides has been demonstrated. This lack of catalytic activity could be due to the presence of an extra copper-binding ligand (Fig. 1(E)) that may prevent the copper from reacting with its oxygen co-substrate, as it is the case in the copper-binding protein CopC (Arnesano *et al.*, 2002; Labourel *et al.*, 2020), and/or to the absence of conserved residues around the copper site that promote polysaccharide binding. Therefore, these proteins cannot be classified as LPMOs. For completeness, it should be mentioned that a very minor fraction of proteins classified into the AA9 family carry a substitution of the N-terminal His by Arg (Lenfant *et al.*, 2017; Yakovlev *et al.*, 2012), which likely renders the protein catalytically inactive (Frandsen *et al.*, 2019).

Notably, genes encoding X325 proteins are widespread among dikaryotic fungi, occurring in 82.3% of Ascomycete and 67.7% of Basidiomycete genomes, and also occur in the early diverging fungal lineages (Table 1). This makes the X325 proteins the second most widespread LPMO/LPMO-like family in fungi after AA11s. The fact that we find X325 genes in all fungal divisions where filamentous growth has evolved, points to a crucial role for these somewhat enigmatic proteins. (Note that the phyla Cryptomycota and Microsporidia, for which no X325 genes have been found so far, contain strictly non-filamentous, intracellular parasites (Naranjo-Ortiz and Gabaldón, 2019)). Currently, LPMO-like proteins are hypothesized to be involved with copper homeostasis during plant biomass decay (Labourel *et al.*, 2020) or host-parasite interactions (García-Santamarina *et al.*, 2020). It is likely that these X325 proteins share a common ancestor with LPMOs but evolved separately prior to the acquisition of polysaccharide cleaving ability. The fact that LPMO-like proteins and AA11 LPMOs occur in nearly all fungal phyla, including Dikarya and early diverging fungi, suggests the importance of their function in the fungal kingdom and indicates that these proteins were among the earliest to evolve from a common ancestor. Furthermore, the varying distribution of LPMO families in the phyla indicates that LPMOs belonging to different families may have evolved at various timepoints, which may indicate different selection pressures for the distinct LPMO families.

Assaying LPMO Catalysis

Characterization of the catalytic activity of LPMOs is complicated by the wide range of possible on- and off-pathway reactions that may take place when mixing reductants, O₂ and/or H₂O₂, an insoluble, not necessarily “clean” and potentially redox active

Fig. 1 Representative structures (A–E) and overall reaction (F) of fungal LPMOs/LPMO-like proteins. Panels A–E show that different LPMO families have a similar β -strand core (left and middle panels) and catalytic center (right panels), while they have evolved distinct substrate-binding surfaces that differ in length and width, as well as ruggedness (left and middle panels), to target different polysaccharides (indicated to the left). The black bars indicate the place of substrate binding for LPMOs (A–D) and the corresponding surface around the copper site for LPMO-like proteins (E). Panel F shows the two types of reaction equations that have been proposed for LPMO catalysis (Bissaro *et al.*, 2017; Vaaje-Kolstad *et al.*, 2010). PDB structures: TAA9A, 2YET; AoAA11, 4MAI (incomplete structure, the only AA11 with structure); AoAA13, 4OPB; PCAA14B, 5N07 (structure without active site copper); LaX325, 6IBJ. Note that there is currently no structure for fungal AA16 LPMOs, and that methylation of His1 lacks in panels B, D and E as these recombinant proteins were not expressed in a filamentous fungal expression host but in *Escherichia coli* (AoAA11 in panel B) or in *Pichia pastoris* (PCAA14B in panel D and LaX325 in panel E), which are unable to methylate the N-terminal histidine. The protein structures are shown in rainbow colors, from blue (N-terminus) to red (C-terminus); the active site copper is indicated by an orange sphere. The crystal structure of the AA14 (panel D) lacks a copper ion.

Fig. 2 The occurrence of fungal LPMOs (AA9, AA11, AA13, AA14 and AA16) and LPMO-like proteins (X325) in fungal phyla, presented on a phylogenetic tree. The numbers in brackets represent the number of individual proteomes deposited in the UniProt Reference Proteomes database for the given phylum. The pie charts show the proportion of proteomes containing one or more copies of a given protein family (in color). The range of gene copies found in phylum-specific proteomes is provided in [Table 1](#).

substrate, the LPMO and, potentially, small amounts of free copper that may change during the reaction. To complicate things even further, the oxidase activity of LPMOs (see above) implies that these enzymes can synthesize their own co-substrate ([Bissaro et al., 2017](#); [Wang et al., 2019](#)). Finally, LPMOs are prone to autocatalytic oxidative damage in their catalytic centers ([Bissaro et al., 2017](#)) and, during an enzymatic reaction, this susceptibility may change over time as the substrate is being depleted. At lower substrate concentrations, the LPMO is more likely to engage in potentially destructive off-pathway reactions. For a detailed description of the many possible pitfalls in characterizing LPMO activity, the reader is referred to a recent review on the topic ([Eijssink et al., 2019](#)) and the references therein. Here, only a few key points are briefly discussed.

Due to the abovementioned complexities, it is imperative that characterization studies are carried out with highly purified LPMOs that are free of other redox enzymes or compounds, and free of transition metals. As to recombinant production of LPMOs ([Gaber et al., 2020](#)), it is important that the expression system is such that the purified enzyme contains the correct N-terminal histidine and that the resulting LPMO preparation is free of contaminating background activities, such as cellulase activity. Complete avoidance of background activity may be difficult, and, in such cases, it is very important to separate between reductant-dependent reaction products, which are LPMO products, and reductant-independent reaction products, which may be generated by background activities. It is advisable to make sure that the LPMO is copper-saturated, and one needs to use a procedure that removes remaining unbound copper after the saturation step.

Typical LPMO reactions are set up aerobically in the presence of low mM amounts of reductant, for example 1 mM ascorbic acid ([Vaaje-Kolstad et al., 2010](#)). In such a setup, the reductant is consumed stoichiometrically either in a monooxygenase reaction or in reactions that generate H_2O_2 , which is then used in a peroxygenase reaction (see above; [Fig. 1\(E\)](#)). Alternatively, reactions can be set up with micromolar amounts of reductant, e.g., 20 μ M ascorbic acid, needed for a so-called priming reduction of the LPMO,

with addition of H_2O_2 . High concentrations of H_2O_2 need to be avoided since these may lead to autocatalytic LPMO inactivation and perhaps to more unspecific generation of reactive oxygen species, which could damage any enzyme in the reaction mixture. Ideally, the concentration of H_2O_2 needs to be kept low by gradually administering it to the reaction, e.g., as done by Müller *et al.* (2018), but this may be technically challenging. *In situ* generation of H_2O_2 by adding glucose oxidase provides a possible solution (Bissaro *et al.*, 2017). Importantly, the catalytic rates observed for typical monooxygenase setups are orders of magnitude lower compared to rates observed for peroxygenase setups (ranging from 0.1 s^{-1} and much below in the former to up to 10 s^{-1} in the latter), as recently reviewed by Bissaro *et al.* (2018).

C1 oxidation of cellulose leads to the generation of lactones, which spontaneously convert to aldonic acids, whereas C4 oxidation leads to the generation of ketones, which spontaneously convert to gemdiols. These products can be identified using mass spectrometry and liquid chromatography, as extensively discussed elsewhere (see (Eijsink *et al.*, 2019), and references therein). It is important to note that C4-oxidized products are unstable at slightly alkaline pH, as discussed in (Westereng *et al.*, 2016). Of note, several groups have published LPMO activity assays that are based on the use of other substrates and other analytical methods. These methods suffer from various limitations, but can nevertheless be very useful, as discussed in (Eijsink *et al.*, 2019) and references therein.

The choice of reductant may have a major impact on the observed LPMO activity, as discussed in Section “Interplay With Other Fungal Redox Enzymes” below and in e.g. (Frommhagen *et al.*, 2016; Kracher *et al.*, 2016). It is important to note that this impact is not necessarily related to the reductants’ varying abilities to reduce the LPMO, but may also relate to effects on the many possible side reactions, such as side reactions leading to the generation or consumption of H_2O_2 .

Due to the many complications, including enzyme inactivation, in both monooxygenase and peroxygenase setups, there are very few studies that describe proper kinetic data for LPMOs. One notable exception is a study by Kuusk *et al.* (2018), who showed that the $k_{\text{cat}}/K_{\text{m}}/\text{H}_2\text{O}_2$ of CBP21, a chitin-active LPMO, is in the order of $10^6 \text{ M}^{-1}\text{s}^{-1}$ and some three orders of magnitude higher than the $k_{\text{cat}}/K_{\text{m}}/\text{O}_2$. Because of the occurrence of side reactions, including enzyme inactivation, progress curves for LPMO reactions are notoriously nonlinear. This obviously implies that it is impossible to draw quantitative conclusions regarding LPMO activity from single-timepoint product formation measurements.

Interplay With Other Fungal Redox Enzymes

LPMOs are copper-dependent redox enzymes and require an electron donor to reduce the active site copper from the Cu(II) to the Cu(I) state before they can perform catalysis either by using molecular oxygen or hydrogen peroxide (Bissaro *et al.*, 2017; Vaaje-Kolstad *et al.*, 2010; Wang *et al.*, 2019). In fungi, reduction of the active site copper can occur either by reducing compounds present at the fungus-plant interface, including fungal secondary metabolites, plant phenols and non-aromatic reducing agents such as ascorbic acid (Frommhagen *et al.*, 2016; Kont *et al.*, 2019; Kracher *et al.*, 2016; Westereng *et al.*, 2015), or by an enzymatic electron donor via direct electron transfer (Garajova *et al.*, 2016; Kracher *et al.*, 2016; Langston *et al.*, 2011; Phillips *et al.*, 2011; Tan *et al.*, 2015).

Early genome studies of dikaryotic fungi showed that genes encoding AA9s often co-occur with oxidoreductases belonging to the AA2, AA3 and AA5 families (Eastwood *et al.*, 2011; Floudas *et al.*, 2012). Analysis of 33 basidiomycete genomes by Riley *et al.* indicated co-evolution of AA9 genes with genes encoding AA3_2 oxidoreductases and AA2 peroxidases through gene duplication or loss, suggesting a potential interaction between these oxidoreductases (Riley *et al.*, 2014). In a later study, comparing the occurrence of oxidoreductases in 47 ascomycete and 50 basidiomycete genomes, Kracher *et al.* (2016) confirmed that AA9 LPMOs often co-occur with AA3_1 cellobiose dehydrogenases (CDH) and AA3_2 oxidoreductases, supporting a potential interplay between these enzymes. In addition, they found lifestyle-specific correlations in the occurrence of cellulolytic and lignin-active enzymes. In particular, they noted a high correlation between the occurrence of hydrolytic cellulases, AA9 LPMOs and AA3_1 CDHs in cellulose-degrading soft-rot fungi, while they noted a correlation between the occurrence of AA1 laccases, AA2 peroxidases and AA3 oxidoreductases (excluding AA3_1 CDHs) in white-rot fungi, which are capable of degrading lignin (Kracher *et al.*, 2016). Corresponding to this, gene evolution analysis by Nagy *et al.* (2016) indicated that cellulose and lignin degradation evolved separately. Ancient Dikarya and Basidiomycota had an extensive repertoire of genes encoding plant cell wall-active enzymes (including AA9 LPMOs) involved in plant cell wall polysaccharide decomposition, while they lacked key enzymes (including AA2 peroxidases) related to lignin decomposition (Nagy *et al.*, 2016). This is consistent with the hypothesis that fungi acquired the capability of lignin degradation only at a later evolutionary stage, i.e., when white-rot fungi evolved (Floudas *et al.*, 2012; Kohler *et al.*, 2015). While from an evolutionary perspective cellulose-active AA9 LPMOs seem to have evolved earlier and separately from enzymes involved in lignin degradation, there is growing evidence for the potential interplay between AA9 LPMOs and lignin-active oxidoreductases in fungal secretomes, as described here below.

Apart from evolutionary connections, AA9 LPMOs have also been found co-regulated with AA3_1 CDHs, which may be indicative of co-operativity between the enzymes (see e.g. (Miyauchi *et al.*, 2020)). Notably, transcriptional regulation of orthologous genes can differ even between species belonging to the same genus, as shown for AA2 peroxidases in three *Pycnoporus* species (Miyauchi *et al.*, 2020). This may indicate species-specific adaptation of (co-)regulation and (co-)secretion of plant cell wall-active oxidoreductases in response to distinct environmental niches. Oxidoreductases, including LPMOs, co-exist in fungal

secretomes and, consequently, are linked through reactive oxygen species, which are formed and consumed continuously as a result of their catalytic actions (Berrin *et al.*, 2017; Bissaro *et al.*, 2018). For example, hydrogen peroxide can be produced by several members of the AA3_2 oxidoreductase family, while it is consumed by both AA2 peroxidases and LPMOs. Indeed, oxidoreductases belonging to families AA1, AA3_1, AA3_2 and AA12 have been shown to drive LPMO reactions, either directly or, in the case of AA1, via redox mediators (Brenelli *et al.*, 2018; Garajova *et al.*, 2016; Kracher *et al.*, 2016; Langston *et al.*, 2011; Perna *et al.*, 2020; Várnai *et al.*, 2018).

Among the oxidoreductases, AA3_1 CDHs were the first ones shown to be able to drive oxidative cleavage of cellulose by LPMOs (Langston *et al.*, 2011; Phillips *et al.*, 2011) and have gained the most attention, which is partly related to the fact that both AA9 LPMOs and CDHs are active on cellulose. CDHs contain a central flavin-dependent AA3 domain and an N-terminal AA8 cytochrome domain that transfers electrons from the reduced flavin to the LPMO, one at a time. In addition, CDHs may contain a C-terminal cellulose-binding domain. CDHs from the ascomycetes *Humicola insolens* (Langston *et al.*, 2011), *M. thermophila* (Phillips *et al.*, 2011), *N. crassa* (Kittl *et al.*, 2012; Sygmund *et al.*, 2012), *P. anserina* (Bennati-Granier *et al.*, 2015) and *Myriococcum thermophilum* (Tan *et al.*, 2015) as well as CDH from the basidiomycete white-rot fungus *Pycnoporus cinnabarinus* (Bey *et al.*, 2013) can drive catalysis by multiple LPMOs from the same species (Bennati-Granier *et al.*, 2015; Kittl *et al.*, 2012; Sygmund *et al.*, 2012) or from other species, including a bacterial chitin-active family AA10 LPMO (Loose *et al.*, 2016).

An AA12 PQQ-dependent pyranose dehydrogenase from *Coprinopsis cinerea* (CcPDH) has been shown to drive LPMO reactions, analogous to FAD-dependent CDHs (Petrović *et al.*, 2019; Várnai *et al.*, 2018). Although most fungal PDHs occur as single-domain enzymes (Takeda *et al.*, 2019), CcPDH shares a similar domain architecture with CDHs, comprising an N-terminal AA8 cytochrome domain, a central AA12 dehydrogenase domain and a C-terminal CBM1 domain. It has been amply demonstrated that the CDH/PDH-driven LPMO reaction depends on direct electron transfer from the AA8 domain to the copper (Breslmayr *et al.*, 2020; Courtade *et al.*, 2016; Tan *et al.*, 2015; Várnai *et al.*, 2018) and that the CDH and LPMO reactions are coupled (Filandr *et al.*, 2020; Loose *et al.*, 2016; Petrović *et al.*, 2019). It is important to note though that the nature of the LPMO-fueling effect of CDH and PDH remains somewhat ambiguous. It cannot be excluded that the rate-limiting contribution of these enzymes to fueling the LPMO reaction relates to their low oxidase activity that leads to generation of H₂O₂. In support of this, a recent study by Kracher *et al.* has shown that LPMO activation by engineered CDH variants is proportional to their rate of H₂O₂ production (Kracher *et al.*, 2020). More generally, the latter results lend further support to the notion that H₂O₂-producing oxidoreductases in fungal secretomes can drive LPMO reactions (Bissaro *et al.*, 2018).

AA3_2 oxidoreductases, which seem to have co-evolved with AA9 genes in basidiomycetes (Riley *et al.*, 2014), have also been confirmed to drive LPMO reactions, either directly (Garajova *et al.*, 2016) or via diphenol/quinone-type redox mediators provided that the mediator is regenerated efficiently by the oxidoreductase (Kracher *et al.*, 2016). Notably, not all these oxidoreductases have the ability to drive LPMO reactions directly (Bissaro *et al.*, 2017; Filandr *et al.*, 2020; Garajova *et al.*, 2016). Two independent studies have shown that an AA3_2 glucose oxidase can drive cellulose oxidation by LPMOs belonging to the AA9 (Filandr *et al.*, 2020) and AA10 families (Bissaro *et al.*, 2017), provided that the active site copper is in its reduced state. Of note, the ability of an oxidoreductase to produce H₂O₂ may not be enough to drive the LPMO reaction, since the LPMO also needs to be reduced. This could be a plausible explanation as to why an AA3_2 aryl-alcohol oxidase was found incapable of promoting LPMO reactions despite being able to generate H₂O₂ (Garajova *et al.*, 2016).

While in artificial systems (i.e., purified enzymes acting on lignin-free cellulosic substrates in the absence of external reducing agents) some oxidoreductases cannot drive the LPMO reaction (Bissaro *et al.*, 2017; Filandr *et al.*, 2020; Garajova *et al.*, 2016), in nature LPMOs are anticipated to be in their reduced form due to an abundance of reducing compounds present at the fungus-plant interface. Notably, a substantial part of plant- or fungus-derived phenols react not only with LPMOs but also with other oxidoreductases present in the fungal secretome. AA3_2 oxidoreductases, for instance, can drive LPMO reactions by recycling diphenol/quinone-type redox mediators (Kracher *et al.*, 2016). In addition, two polyphenol oxidases have been shown to promote LPMO reactions by converting lignin-derived monophenols to diphenols, which react more readily with LPMOs (Frommhagen *et al.*, 2017). It is important to note the complex spectrum of multiple roles that lignin may play in these processes. Brenelli *et al.* have shown that low-molecular weight lignin fractions generated with laccase-mediator systems can drive LPMO catalysis (Brenelli *et al.*, 2018). Recently, lignin-derived compounds were shown to serve both as an electron donor for LPMOs, reducing the active site copper, and as a source of H₂O₂, which is generated through the reaction of these compounds with molecular oxygen (Kont *et al.*, 2019). Correspondingly, Perna *et al.* have observed that laccase-catalyzed oxidation of lignin and lignin building blocks, which generates radicals, promotes H₂O₂ production and, consequently, boosts the LPMO reaction (Perna *et al.*, 2020), thereby expanding further the network of interactions between LPMOs and other oxidoreductases. Potential interactions between LPMOs, other oxidoreductases and reactive oxygen species have been extensively reviewed by Bissaro *et al.* (2018).

As alluded to above, analysis of predicted or actual fungal secretomes may provide insight into how LPMOs and potential redox partners collaborate during plant biomass conversion. It is worth noting that such analysis also provides a powerful tool for identifying novel LPMOs with potentially crucial roles in the degradation process. Such LPMOs may belong to established families with high gene multiplicity or belong to hitherto undiscovered LPMO families (Berrin *et al.*, 2017). Indeed, several secretome studies have led to the identification of new LPMO families (Couturier *et al.*, 2018; Filiatrault-Chastel *et al.*, 2019; Sabbadin *et al.*, 2018) or redox partners of LPMOs (Frommhagen *et al.*, 2017; Garajova *et al.*, 2016). Time-resolved analysis of fungal secretomes, in particular, can give more detailed insight into the intricate network of plant cell wall-active enzymes and increase the probability

of identifying the most important LPMOs in various phases of the degradation process, as well as biologically relevant redox partners of such LPMOs (e.g. (Navarro *et al.*, 2014; Presley and Schilling, 2017)).

Applications: Cellulose Saccharification and Fibrillation

Since the discovery that *T. reesei* was responsible for degrading cotton army tents during World War II, there has been a great interest in the application of fungal cellulase systems for saccharification of cellulose-rich biomass. One possible reason for LPMOs not having been discovered earlier may be that *T. reesei* contains only few LPMO genes and that only low amounts of LPMOs are present in *T. reesei* secretomes. On the other hand, already in 1950, Reese, who lent his name to *T. reesei*, and co-workers presented the so-called C_1 - C_X theory, suggesting that efficient hydrolytic conversion of cellulose by cellulases (C_X) required some sort of enzymatic activation step, catalyzed by C_1 , that makes cellulose more accessible (Reese *et al.*, 1950). Combining this hypothesis with the observation, in 1974, that oxygen promotes cellulose degradation (Eriksson *et al.*, 1974) and the discovery of LPMOs in 2010 (Vaaje-Kolstad *et al.*, 2010) leads to the suggestion that LPMOs catalyze the C_1 step. More recently, Navarro *et al.* have shown early secretion of seven AA9 LPMOs of *Laetisaria arvalis* (a soil-inhabiting basidiomycete containing 16 AA9-encoding genes) in response to growth on cellulose, suggesting that some LPMOs secreted by fungi may indeed act in the first phase of the cellulose degradation process (Navarro *et al.*, 2014).

After the initial discovery of bacterial LPMO activity in 2010 (Forsberg *et al.*, 2011; Vaaje-Kolstad *et al.*, 2010), several research groups demonstrated that fungal LPMOs (then named GH61s) could cleave cellulose (Beeson *et al.*, 2012; Langston *et al.*, 2011; Phillips *et al.*, 2011; Quinlan *et al.*, 2011; Westereng *et al.*, 2011). This initiated many studies on the roles of LPMOs in saccharification of cellulose by cellulase cocktails and also resulted in the use of LPMOs in the latest generations of commercial enzyme cocktails (Johansen, 2016). In practice, this research work typically involved spiking fungal secretomes low in LPMO activity (in-house prepared or commercial) with monocomponent LPMOs. Before the catalytic activity of LPMOs was known, it had been shown that these proteins can boost the activity of chitinases (Vaaje-Kolstad *et al.*, 2005) and cellulases (Harris *et al.*, 2010; Merino and Cherry, 2007). Harris *et al.* (2010) showed that cloned and purified LPMOs from *Thielavia terrestris* and *Thermoascus aurantiacus* could increase the saccharification yield of lignocellulosic biomass by a cocktail of *T. reesei* cellulases. The first study that linked improved saccharification to LPMO activity was a 2011 study by Westereng *et al.* (2011). Here it was shown that addition of an LPMO from *Phanerochaete chrysosporium* to Celluclast, a commercial cellulase preparation, could improve the saccharification yield of cellulose by about 30%, and that this positive effect was linked to LPMO activity, which was measured as production of C_1 -oxidized sugars. Several LPMO-spiking studies have confirmed the positive effect of LPMOs on saccharification of cellulosic substrates by commercial enzyme preparations (Cannella *et al.*, 2012; Chylenski *et al.*, 2017; Hu *et al.*, 2014, 2013, 2015; Müller *et al.*, 2015). Interestingly, one of these studies indicated that the optimum concentration of LPMOs in a cellulase cocktail could be as high as 15% on a protein basis (Müller *et al.*, 2015) (Fig. 3).

Importantly, the inclusion of LPMOs in modern enzyme blends also affects process design since these enzymes require an oxygen co-substrate and reducing equivalents. This was nicely illustrated in a 2015 study by Müller *et al.* (2015), as explained in the legend of Fig. 4. Concerning the production of ethanol, the role of LPMOs also affects the choice between a so-called Separate

Fig. 3 Increase in saccharification yield and production of oxidized sugars upon supplying a commercial cellulase mixture with an LPMO. Steam-exploded birch wood at 100 g/L (dry matter basis) was incubated with a mixture of Celluclast, an LPMO-poor cellulase mixture, and Novozym 188, a β -glucosidase, ("C/β") for 20 h. Various fractions (0%–20%) of this enzyme cocktail were replaced by purified TaAA9A (also known as TaGH61A or TaLPMO9A) from *T. aurantiacus*. Black bars show the increase in glucose release (in %) compared to the Celluclast/Novozym 188 mixture alone, whereas the white bars show the concentration of oxidized sugars in the product mixtures. For comparison, the results for a reaction with Cellic™ CTec2 ("C. CTec2"), a modern LPMO-containing cellulase cocktail are included. This Figure is reproduced from Müller, G., Várnai, A., Johansen, K.S., Eijssink, V.G.H., Horn, S.J., 2015. Harnessing the potential of LPMO-containing cellulase cocktails poses new demands on processing conditions. *Biotechnology for Biofuels* 8, 187.

Fig. 4 Saccharification of Avicel (A, B) or steam-exploded birch wood (C, D) at 100 g/L (dry matter) under aerobic ("Air") or anaerobic ("N₂") conditions in the presence ("+") or absence ("-") of ascorbic acid. The *left panels* (A, C) show glucose concentrations at two time points, while the *right panels* (B, D) show production of the primary oxidized product, Glc4gemGlc, at the same time points. The *blue bars* represent 4 h of incubation, while *red bars* represent 18 h. Note that the presence of oxygen promotes both LPMO activity and glucose release. In the case of a "clean" substrate, LPMO activity requires an added reductant (ascorbic acid; panels A & B), whereas reduction can be provided by the substrate when the substrate is rich in lignin (panels C & D). This Figure is an adapted combined version of two figures appearing in Müller, G., Várnai, A., Johansen, K.S., Eijsink, V.G.H., Horn, S.J., 2015. Harnessing the potential of LPMO-containing cellulase cocktails poses new demands on processing conditions. *Biotechnology for Biofuels* 8, 187.

Saccharification and Fermentation (SHF) process and a so-called Simultaneous Saccharification and Fermentation (SSF) process. Generally, using an SHF setup seems preferable over an SSF setup since fermenting organisms will consume O₂ in SSF and thus limit LPMO activity (Cannella and Jørgensen, 2014; Müller *et al.*, 2017).

The finding that H₂O₂ can be used to obtain efficient LPMO reactions has (obviously) been explored in optimization of biomass conversion studies. In a landmark study by Müller *et al.*, it was shown that, indeed, reactor setups with controlled addition of H₂O₂ can be very efficient (Müller *et al.*, 2018). However, so far, such positive results have only been described for clean, cellulose-rich and lignin-poor substrates. It has so far not been possible to harness the ability to speed up LPMO reactions by controlled addition of H₂O₂ in reactions with "real" biomass, as exemplified by Müller *et al.* (2018), who studied saccharification of steam-exploded birch wood. In a recent study, the approach of controlled addition of H₂O₂ to reactions with lignin-poor substrates, in this case sulfite-pulped spruce wood, was shown to be successful at demonstration scale (Costa *et al.*, 2020).

Overall, the inclusion of LPMOs in cellulase cocktails has been a great success, significantly improving enzymatic saccharification of lignocellulosic substrates. Further improvements of the current enzyme blends and processes might involve optimization of LPMO/cellulase ratios for different substrates and optimization of H₂O₂ addition regimes (or *in situ* H₂O₂ production). It is clear that the synergy between LPMOs and cellulases depends on the enzymes, the substrate and the redox conditions (Kadić *et al.*, 2019; Müller *et al.*, 2018; Tokin *et al.*, 2020).

Recent advancements in our understanding of how LPMOs accelerate saccharification of recalcitrant plant biomass by cellulases have shed light on the impact of LPMO treatment on substrate structure and, consequently, the application potential of LPMOs for surface modification and/or fibrillation of wood fibers. Initial molecular dynamics simulations by Vermaas *et al.* indicated that

accumulation of oxidized groups on the surface of crystalline cellulose by LPMO action (in particular carboxyl groups introduced by C1-oxidizing LPMOs) disrupt the structure of crystalline cellulose, reducing the decrystallization penalty for processive cellobiohydrolases (Vermaas *et al.*, 2015). Shortly thereafter, Villares *et al.* provided experimental proof, by solid-state NMR and atomic force microscopy (AFM), that the action of the C1/C4-oxidizing PaLPMO9H from *P. anserina* introduces changes in the regions connecting elementary fibrils, thus promoting fibrillation at micro- and nanoscale that becomes visible after mechanical fibrillation (Villares *et al.*, 2017). Furthermore, Eibinger *et al.* showed partial detachment of cellulose chain bundles, i.e. fibrillation of cellulose, at the tips of cellulose nanocrystals upon the action of the C1-oxidizing NcLPMO9F (but not of the C4-oxidizing NcLPMO9C) from *N. crassa* using real-time AFM (Eibinger *et al.*, 2017). Later, Hu *et al.* (2018) confirmed that treating a cellulose pulp with the C1/C4-oxidizing TaLPMO9A from *T. aurantiacus* leads to an increase in acid group content of the pulp (presumably by formation of carboxyl groups generated during C1-oxidation), which corresponded to an increase in the stability of the fiber suspension (Hu *et al.*, 2018). In addition to cellulose-active LPMOs, recently two xylan-specific AA14 LPMOs have been shown to contribute to cellulose fibrillation using AFM and transmission electron microscopy (TEM), presumably by cleaving recalcitrant xylan adhering to cellulose microfibrils (Couturier *et al.*, 2018).

There may be differences between the mechanisms that underlie apparent promotion of fibrillation by LPMOs, which could relate to regioselectivity (Eibinger *et al.*, 2017; Vermaas *et al.*, 2015; Villares *et al.*, 2017) and substrate specificity (Couturier *et al.*, 2018; Ladevèze *et al.*, 2017). Still, it is now clear that LPMOs belonging to various families, including AA9, AA10 and AA14, can promote and even induce fibrillation. Currently, endoglucanases (GH45s) are routinely applied as a fibrillation aid in industry (Marjamaa and Kruus, 2018). LPMOs, which use a fundamentally different mechanism from that of endoglucanases (i.e. combining cleavage of chains and introduction of oxidized groups at the fiber surface), provide an alternative tool for fibrillation of wood fibers and for surface modification of wood fibers (e.g. (Hu *et al.*, 2018; Koskela *et al.*, 2019; Valenzuela *et al.*, 2019)). Multiple recent studies have confirmed this potential, especially for improving mechanical fibrillation during nanocellulose production, for various materials, including cotton linters (Valls *et al.*, 2019), flax fibers (Valenzuela *et al.*, 2019), hardwood fibers (Moreau *et al.*, 2019) and softwood fibers (Koskela *et al.*, 2019). Further studies are warranted, for example to understand how the regioselectivity and substrate specificity of LPMOs relate to their plant cell wall-loosening (fibrillating) function, as well as how H₂O₂ may be used to improve the efficiency of LPMOs in fiber modification.

Future Perspectives

Ten years after their discovery, LPMOs are at the center of research on enzymatic conversion of biomass and considered a central component of fungal cellulolytic secretomes. Despite recent progress, many questions remain, for example related to the catalytic mechanism, the structural basis of substrate specificity, the degree and biological relevance of functional variation, the interplay with other redox enzymes and optimal application of these enzymes in industrial biomass processing. The plethora of LPMOs found in several fungal lineages suggests that there is a lot more to discover, including, most likely, novel functionalities. The occurrence of LPMO-like copper-binding proteins in many fungal species is intriguing and one may wonder about the possible interplay between these proteins and catalytically active LPMOs. Likewise, one may wonder about how multiple LPMOs in fungal secretomes collaborate (as shown for an AA14 and an AA9 LPMO (Couturier *et al.*, 2018)), and maybe even synergize, during biomass conversion; this aspect of LPMO multiplicity remains unexplored.

When (re-)assessing existing LPMO literature, especially literature published prior to 2018, it is important to be aware of the potentially different roles of O₂ and H₂O₂ as co-substrates and of the ongoing scientific debate regarding the role of these substrates. For example, one could ask whether the huge variation between reductants in terms of their ability to drive LPMO reactions in the presence of oxygen could be due to variation in the efficiency of *in situ* generation of H₂O₂ rather than different abilities to reduce the LPMO. In this respect, it is interesting to note the recent study by Kracher *et al.* (2020), who showed that an engineered variant of CDH with increased oxidase activity (i.e., increased production of H₂O₂) is more efficient in driving LPMO reactions compared to the wild-type enzyme.

As alluded to above, there is functional data for multiple LPMOs from the same fungal species, providing some insight into functional variation among LPMOs produced by the same organism. However, it must be noted that we currently do not have a full picture of the “LPMO potential” for any fungus; i.e. we do not know the complete catalytic potential of a complete set of LPMOs from a single fungus. Likewise, while both the distribution of genes and the properties of characterized LPMOs seem to indicate that the substrate specificities of LPMOs correlate with fungal lifestyle, there is currently too little information for substantiating this (expected) correlation.

To obtain a more complete picture of the fungal “LPMO potential”, more LPMOs need to be characterized. Such characterization should include accurate (and challenging) kinetic analyses as well as thorough mapping of substrate specificity towards all potentially relevant substrates, varying from pure cellulose to a wide variety of co-polymeric structures that may occur in the plant and fungal cell walls. Further insight into the natural redox partners of LPMOs is also of great interest, one question being whether LPMOs belonging to different families or expressed during different phases of plant cell wall degradation may have different (preferred) redox partners. For example, although CDH is established as a natural redox partner of AA9 LPMOs, little is known about the natural redox partners of fungal LPMOs in the other AA families. While additional information may come from expression studies showing which LPMOs and other redox enzymes are co-expressed during growth on different substrates, functional characterization of individual enzymes is a prerequisite for further progress.

Introduction

The bio-based economy requires the use of renewable resources for the production of biochemicals and biomaterials, for which lignocellulosic biomass is becoming a valuable feedstock (Furtado *et al.*, 2014). Lignocellulose is a collective name for an inedible plant material containing polysaccharides, cellulose and hemicelluloses, and the aromatic polymer lignin. Every year, millions of tons of lignocellulosic biomass are being produced as a low-value byproduct from agroforestry, e.g., corn stover, straw, cotton seed hulls and wood sawdust, most of which end up being burned or discarded. However, when broken down to its constituent monomers, lignocellulosic biomass becomes an abundant and attractive source of fermentable sugars and aromatics, which can be used for sustainable production of valuable compounds, including biofuels and chemicals.

Cellulose, the most abundant polymer in lignocellulose (35%–50% of dry weight), is a linear polymer of glucose that can be directly fermented for the production of 2nd generation ethanol (Anwar *et al.*, 2014; El-Naggar *et al.*, 2014). Despite its simple composition, natural cellulose forms long crystalline microfibrils that are cross-linked to lignin through hemicelluloses, which makes glucose extraction rather difficult. As filamentous fungi are the most prominent lignocellulose degrading microorganisms and often have high capacity for enzyme secretion, their cellulose degrading enzymes have been a focal point of intensive research. This has made fungal cellulases important industrial enzymes with applications far beyond biorefinery and led to, e.g., several commercial cellulase formulations that can be used in different industrial contexts (Kuhad *et al.*, 2011).

In this chapter, we summarize information about cellulose and cellulose-degrading enzymes produced by fungi with examples of their current applications in food, feed, brewing, textile, laundry, and biorefinery industries. Moreover, we discuss how fungal cellulases and their production could be improved to meet the requirements of the competitive biotechnology market.

Cellulose

Cellulose is the major component of lignocellulose and the most abundant renewable polymer on earth. In addition, cellulose exists in the cell walls of algae (Samiee *et al.*, 2019) and oomycetes (Fugelstad *et al.*, 2009), and is produced by certain bacterial species (Wang *et al.*, 2019). It is a water-insoluble homo-polysaccharide composed of repeated β -D-glucopyranose (D-glucose) residues that are linked by β -1,4 glycosidic bonds. The cellulose polymer contains linear glucan chains consisting of up to 25,000 D-glucose residues. Cellulose microfibrils are formed when 15–45 parallel, unbranched glucan chains are joined by intermolecular hydrogen bonds. The cellulose microfibrils are cable-like bundles that have a high tensile strength and contain crystalline, paracrystalline and amorphous regions. Of these, the crystalline conformation of cellulose is the most recalcitrant making it highly resistant to enzymatic degradation (Held *et al.*, 2014).

In plant cell walls, the cellulose microfibrils are stabilized by hydrogen bonds and are surrounded by hemicellulose polymers that provide further structural strength by linking cellulose fibers into microfibrils. Hemicelluloses are the second most abundant polysaccharides in lignocellulose and, different from cellulose, they have a highly variable structure containing several heteropolymers of different five- and six-carbon monosaccharide units, i.e., pentoses (D-xylose, L-arabinose) and hexoses (D-mannose, D-glucose, D-galactose, L-rhamnose) that additionally can be acetylated (Klemm *et al.*, 2005). The cellulose-hemicellulose matrix is cross-linked through hemicellulose with lignin, an insoluble aromatic polymer and the most recalcitrant polymer of plant biomass, which provides structural reinforcement to the plant tissue and resilience to biological and physical attacks (Lacayo *et al.*, 2013; Barros *et al.*, 2015). This molecular architecture gives enormous stability to lignocellulose and makes the exploitation and further processing of its individual polymers challenging.

Cellulose Hydrolyzing Enzymes

Many fungi are natural decomposers that feed on plant biomass. They break down the complex cellulose polymers to D-glucose through concerted enzymatic action of different cellulases. The so-called classical cellulases are hydrolyzing enzymes which cleave the β -1,4 glycosidic bond in cellulose to release D-glucose monomers, cellobiose or cellooligosaccharides, and include endo-1,4- β -D-glucanase (EGL), exoglucanase and β -glucosidase (BGL) (Kumar *et al.*, 2008). The main representatives of exoglucanases are cellobiohydrolases (CBH) that release disaccharide cellobiose from the ends of the oligosaccharides (Fig. 1), while EGLs (EC 3.2.1.4) randomly hydrolyze the O-glycosidic bonds in cellulose chains resulting in long glucan chains (oligomers) of different length. There are two types of CBHs, acting unidirectionally on the long chain oligomers: CBHI (EC 3.2.1.176) cleave from the reducing end and CBHII (EC 3.2.1.91) from the non-reducing end of the oligosaccharide chain. The processivity, i.e., the average number of cleavages that the enzyme performs on a cellulose chain before it dissociates from the chain, has been reported to differ between fungal CBHs. While

Fig. 1 Hydrolytic degradation of cellulose requires the complementary action of endo-1,4- β -D-glucanases (EGLs), cellobiohydrolases (CBHs) and β -glucosidases (BGLs). Oxidative enzymes, such as lytic polysaccharide monooxygenases (LPMOs), help to break the polymer by rendering access for CBHs and EGLs. NR = non-reducing end; R = reducing end.

processivity is possibly needed for effective degradation of crystalline cellulose, it decreases the speed of the overall hydrolysis (Igarashi *et al.*, 2011). The liberated cellobiose molecules are further hydrolyzed to D-glucose by BGLs (EC 3.2.1.21). Recently, lytic polysaccharide monooxygenases (LPMOs) that together with cellobiose dehydrogenase (CDH, EC 1.1.99.18) oxidatively cleave crystalline cellulose and render access to EGLs and CBHs, have been reported from various fungal species. We do not address LPMOs in this chapter, as they have recently been reviewed, e.g., by Chylenski *et al.* (2019) and Eijsink *et al.* (2019).

The three main cellulase enzymes belong to the glycoside hydrolase (GH) family of the Carbohydrate-Active enZymes Database (CAZy; “see Relevant Website section”; Lombard *et al.*, 2014), in which enzymes are classified into amino acid sequence-based (sub-) families. Fungal EGLs are found in families GH5–10, 12, 26, 44, 45, 48, 51 and 74, whereas CBHs are present in GH5–7 and 48, and BGLs in GH1–3, 5, 9, 16, 30 and 39. Often these cellulases exhibit a specific two domain structure, with the catalytic domain (CD) connected by a peptide linker to the cellulose binding domain (CBD) or carbohydrate binding module (CBM). The CD contains the catalytic site of the enzyme, whereas the CBD/CBM facilitates the binding of the enzyme to its substrate.

Biotechnological Applications of Fungal Cellulases

Over many decades, cellulases have been utilized in various industrial applications making them the third most significant industrial enzymes on the global market after amylases and proteases (Menendez *et al.*, 2015). Use of enzymes is advantageous compared to chemical and mechanical processing, since enzymes are recoverable, specific, low in energy requirements and nonpolluting. In this context, cellulases can be widely applied in different industries including paper and pulp, detergent, and food and feed industries, among others (Fig. 2, Table 1). In the following sections, we will present and give examples of the biotechnology applications in which fungal cellulases are used.

Fungal Cellulases in Food, Feed and Beverage Industries

Food, feed and beverage industries are considered the major industries due to their significant contribution toward basic demands of people around the globe. The food processing industry, i.e., utilization of methods to turn fresh food into a product, is needed to retain or improve nutritional qualities of food, eliminate human health concerns and extend food storage time. In addition, processing improves food flavor, color and texture, and makes the packaging more convenient to handle (Anoop Kumar *et al.*, 2019). To achieve these targets, fungal enzymes have been successfully used in several applications involving plant-derived products. Cellulase complex - CBH, EGL and BGL - in combination with pectin and hemicellulose-acting enzymes comprise macerating enzymes that have important role, e.g., in the extraction of olive oil (Ricochon and Muniglia, 2010; Sharma *et al.*, 2015). The use of enzymes improves yield, enhances quality, increases the level of antioxidants, lowers probability of rancidity, and reduces wastage of starting material (Peres *et al.*, 2017). Additionally, as fruits in their natural form tend to rot fast, and processing them to juice or puree increases their shelf life, the addition of macerating enzymes yields better products and reduces browning (Sims and Bates, 1994). Cellulases also benefit the baking processes by reducing the size of cellulose fibers present in wheat and rye, which in turn softens the dough and reduces water absorption allowing for shorter baking times (Altunel and Ünal, 2017). Most cellulolytic enzymes used in the baking industry to break up roughage in dough originate from the ascomycete fungi *Aspergillus niger*, *Trichoderma reesei* and *Humicola insolens* (Fernandes, 2018).

Animal feed industry is another important branch in the global food industry by enabling large-scale livestock production resulting in increased availability of animal-based products to meet their rising demand. Lignocellulose biomass in form of, e.g., stover and straw

<i>Trichoderma reesei</i>	Enzymatic saccharification of cellulose Enzymatic wash/denim polishing Bio-finishing of cotton textiles Bio-ethanol production Paper recycling Deinking of paper waste	CBHI (CEL7a) Acidic cellulase/neutral EGL CBHI/II EGL/CBHI EGL/III EGL	(Divne <i>et al.</i> , 1994) (Kuhad <i>et al.</i> , 2011) (Miettinen-Oinonen <i>et al.</i> , 2005) (Ellilä <i>et al.</i> , 2017) (Dienes <i>et al.</i> , 2004) (Oksanen <i>et al.</i> , 2000)
<i>Trichoderma harzianum</i>	Degradation of cell wall of plant pathogens Saccharification of lignocellulosic materials	EGL BGL	(Lorito <i>et al.</i> , 1994) (da Silva Delabona <i>et al.</i> , 2013)
<i>Trichoderma viride</i>	Detergent additive	EGL	(Thapa <i>et al.</i> , 2020)
<i>Trichoderma longibrachiatum</i>	Biocontrol agent	EGL	(Migheli <i>et al.</i> , 1998)

has been used as animal feed for a long time, consisting mainly of low soluble carbohydrates and high content of fibers composed of cellulose, hemicellulose and lignin. Due to their symbiotic bacteria and fungi that are able to degrade cellulose and convert it into fatty acids, ruminants, e.g., cattle and sheep, can use plant biomass based feed for development and growth (Schingoethe *et al.*, 1999; Vicini *et al.*, 2003). However, the cellulose digesting ability of many mammals is very limited due to the absence of plant cell wall degrading enzymes. Thus, the major application of cellulases in the feed sector is to convert lignocellulose or plant materials into a more digestible

form. Commercial enzyme preparations, e.g., C500® (BIO-CAT, USA) that originates from *T. reesei* and *A. niger*, consist of cellulase mixtures and increase digestibility of grain and fiber by cleaving cellulose to smaller oligosaccharides and free glucose. Furthermore, various enzyme mixtures consist of both cellulases and xylanases, and break down cellulose and hemicelluloses present in the plant cell wall material. These preparations include, e.g., RONOZYME® MultiGrain, ROXAZYME® G2, RONOZYME® WX and RONOZYME® VP that are commercially available from DSM (The Netherlands). These enzymes can also be utilized to produce animal feed from other agricultural waste residues, such as rice bran, wheat straw and ficus fruit (Hatakka *et al.*, 1989; de Vries *et al.*, 2012).

The beverage industry is the largest food processing industry comprised of segments including alcoholic and non-alcoholic drinks. Approximately 90% of commercially sold ethanol is produced from natural sugars (e.g., D-glucose, D-fructose, sucrose) and starch present in plant cells (Alternative Fuels Data Center: Ethanol Production, 2019). As cellulose and hemicelluloses are composed of sugar monomers, the enzymatic breakdown of lignocellulosic biomass to fermentable sugars that can be used for production of alcohol has attracted attention.

In wine production, the addition of enzyme cocktails with a broad range of activities, such as hemicellulases, cellulase and pectinase, during the extraction process results in increased extraction and filtration rate, while consuming lower energy for the fermentation process to result in better wine stability with decreased viscosity (Villettaz, 1993; Bamforth, 2009; Espejo, 2021). Especially BGLs are used in the process of wine making, since they help releasing volatile compounds like terpenes, which are bound to glucoside fractions derived from grapes and skins, thus improving the aroma of Cabernet Sauvignon and Merlot (Francis *et al.*, 1998). One example are the BGLs from the ascomycete fungus *Aureobasidium pullulans*, which have a good activity at low temperature and seem to improve the wine aroma (Baffi *et al.*, 2013). Identification of an ethanol tolerant EGL from an *A. niger* strain isolated from a wine fermentation cellar demonstrated acidic pH optimum and good thermostability, thus having great potential for simultaneous saccharification (i.e., degradation of polymeric biomass into simple sugars) and ethanol fermentation (i.e., conversion of simple sugars into ethanol) (Xue *et al.*, 2018). Another important sector in the beverage industry includes the production and processing of juices.

Fruit juice is a product for direct consumption with the largest quantity of processed mature fruits by extraction (pressing or diffusion) of cellular content from fruit. In order to minimize the energy consumption during the extraction process and avoid incomplete extraction where part of juice is retained in pomace, enzymatic treatment is applied during the first step of fruit processing (Danalache *et al.*, 2018). Mash treatment uses pectinases in combination with cellulases and hemicellulases to produce pulps, nectars, and turbid or clear juices from various raw materials, such as apples, pears, stone fruits, berries and citrus fruits. The macerating enzymes acting on the soluble pectin and other cell wall polysaccharides allow the production of juice with lower viscosity (Bhat, 2000). Use of crude cellulases obtained from the fermentation fractions of the ascomycete species *Penicillium oxalicum* and *T. reesei* for juice extraction from tomatoes resulted in enhanced yield of carotenoids with possible application as coloring agent in the food and beverage sector (Strati and Oreopoulou, 2014). Moreover, cellulase-based enzymatic hydrolysis of polysaccharides that are present in roasted coffee can be used as a cheaper and more environmentally friendly alternative to the energy-consuming thermal hydrolysis, and was tested with commercial enzyme preparations Celluclast (Novozymes A/S, Denmark), Powercell and Cellumax (Prozyn Biosolutions) in the production of instant coffee powder (Kumar, 2015).

Textile and Detergent Industries

Cellulases are one of the most common enzymes that are used in the textile industry. Novozymes A/S and DuPont (USA) are the key cellulase producers supplying these enzymes to the global market for industrial applications. Their main applications include biopolishing or biofinishing (e.g., depilling and hairiness removal) of cellulose-based fabrics, and biostoning (e.g., softening and fading) of denim. Biofinishing of cellulose-based fabrics with cellulases started in the 1980s and early 1990s. The removal of the surface fuzz from cellulose fibrils and microfibrils by enzymatic treatment results in superior hand-feel and finishes on rayon, linen and cotton knits. Decreased hairiness and increased evenness was observed after treatment of cotton yarns with purified *T. reesei* EGLs (Pere *et al.*, 2001). In addition, a fabric knitted from the enzymatically treated yarn showed decreased tendency towards pilling and higher moisture absorption (Behera *et al.*, 2017). The textile industry requires the enzymes to have process-appropriate biochemical properties, such as increased tolerance towards temperature and pH. Thermostable cellulases with many commercial applications are produced by *A. niger*, *H. insolens*, *Trichoderma viride*, *Trichoderma harzianum* and *T. reesei* (Karmakar and Ray, 2011).

Cellulases are used in the laundry and detergent industry mostly in a mixture with lipases and proteases. The ability of cellulases to remove small fuzzy fibrils from the surface of fabric leads to an improved performance of laundry detergents and results in improved color, brightness and texture. They can also enhance fabric quality, restore fabric softness and remove dirt from textiles. For example, alkaline cellulases from *H. insolens* remove soil particles present in interfibrillar spaces due to their ability to specifically and selectively interact with cellulose in the fiber space of cotton, flax, hemp and jute. In order to enhance the stability of cellulases in liquid detergents, anionic or non-ionic surfactants, citric acid or water soluble salt, proteolytic enzymes and mixtures of propanediol, and boric acid or its derivatives can be used (Behera *et al.*, 2017). In detergents, mainly EGLs originating from *T. reesei*, *T. viride*, *T. harzianum* and *A. niger* are used as additives (Thapa *et al.*, 2020).

Pulp and Paper Industry

Application of cellulases in the pulp and paper industry aims to, e.g., reduce the use of energy, improve paper quality and decrease the environmental burden caused by the pulping process. Reduced energy consumption in refining and improved pulp properties have been achieved by pretreating pulp with cellulases (García *et al.*, 2002; Kim *et al.*, 2006; Gil *et al.*, 2009). Significantly improved pulp

drainage for recycled kraft pulps was reported even at low dosage levels of *T. reesei* EGLs (Oksanen *et al.*, 2000). Also, *T. reesei* EGLs were detected to decrease pulp viscosity, but resulted in negative effect on tensile properties (Pere *et al.*, 1995).

A large number of chemicals are needed for deinking of recycled paper, making it an environmentally harmful and costly process (Virk *et al.*, 2013). To reduce the negative environmental impacts, use of cellulases, alone or together with xylanases, has been proposed as a sustainable alternative for deinking of different types of paper waste. The enzymatic treatment releases ink particles by partially hydrolyzing the fiber surface. This can also increase the relative hydrophobicity of the ink particles by removing small fibrils from their surface, which assists the separation of the particles during washing (Jackson *et al.*, 1996). In addition, the use of enzymes can lead to improvement of, e.g., dewatering and optical properties of pulp, but their excessive use may decrease paper strength and thus needs to be avoided.

The type of cellulase as well as the presence of a CBM have also been suggested to be important factors affecting the properties of enzyme-treated pulp from recycled paper (Dienes *et al.*, 2004). However, some cellulases, such as the commercial enzyme mixture Cellulast 1.5 (Novozymes A/S) derived from *T. reesei*, Iogen cellulase (Iogen, Canada) and a cellulase mixture of *T. viride* CCM1 84, have been shown to both remove ink and improve paper strength (Pala *et al.*, 2004). Cellulases from other *Trichoderma* species tested for deinking include a crude mixture of *T. harzianum* cellulases and xylanases that was able to remove ink from photocopier wastepaper pulp (Pathak *et al.*, 2015). In addition, an enzyme mixture consisting of cellulase and xylanase activities from *Trichoderma longibrachiatum* MDU-6 effectively removed chromophores, phenolics and hydrophobic compounds from newspaper pulp, but did not show significant deinking of examination or laser-printed paper pulps (Chutani and Sharma, 2016). The use of cellulases in pulp and paper industry would benefit from tailor-made enzymes and/or enzyme mixtures having more suitable biochemical properties, e.g., with respect to specificity and optimum pH.

Biorefineries

Cellulases play an essential role in converting lignocellulosic plant biomass feedstocks to biofuels and biochemicals in sugar platform based biorefineries. However, before the enzymatic depolymerization of cellulose and the subsequent fermentation or metabolic conversion of the released glucose molecules to valuable compounds, the recalcitrance of the lignocellulose matrix needs to be overcome. Thus, a pretreatment of lignocellulose either by physical, chemical or biological methods (for more details see, e.g., review by Seidl and Goulart, 2016) remains an essential step in these processes.

In biorefineries, cellulase cocktails are used, as a single cellulolytic enzyme cannot degrade the biomass efficiently enough, and often these cocktails aim to take advantage of the synergy between their monocomponent enzymes. In addition, one enzyme mixture is not optimal for different biomasses that vary in their chemical composition. Several commercial cellulase preparations are available for biorefineries and they typically have CBH as the major activity for degradation of crystalline cellulose (Champreda *et al.*, 2019). Most of the commercially available cellulases for biomass degradation are produced from derivatives of the hyper-cellulolytic *T. reesei* RUT-30 mutant strain (Peterson and Nevalainen, 2012). As *T. reesei* possesses, e.g., low BGL, hemicellulase and LPMO activities, its cellulases have been supplemented with activities from other fungi, such as those from the ascomycete species *Aspergillus awamori* (Gottschalk *et al.*, 2010), *Aspergillus aculeatus* (Suwannarangsee *et al.*, 2012), *Chaetomium globosum* (Wanmolee *et al.*, 2016), *H. insolens* (Kogo *et al.*, 2017) and *Penicillium funiculosum* (van Wyk, 1999), and the basidiomycete species *Laetiporus sulphureus* and *Pleurotus ostreatus* (Valadares *et al.*, 2016).

Other fungi used as sources for commercial cellulases applicable for biorefineries include *Talaromyces cellulolyticus* (formerly known as *Acremonium cellulolyticus*) and different *Penicillium* species. Compared to *T. reesei*, *T. cellulolyticus* produces higher BGL activity and has been shown to be effective in hydrolyzing different lignocellulose feedstocks (Fujii *et al.*, 2009). Several *Penicillia* have also been reported to produce enzyme mixtures that have better properties than *T. reesei* cocktails (Vaishnav *et al.*, 2018). *P. funiculosum* secretes CBH, EGL and BGL activities in well-balanced proportions (de Castro *et al.*, 2010), and CBHI from a hyper-cellulolytic *P. funiculosum* strain has been proposed as an alternative for the corresponding *T. reesei* enzyme in industrial cellulase cocktails (Ogunmolu *et al.*, 2017).

Further development of the properties and production of individual cellulases and their mixtures is still needed to make the biorefinery processes economically viable. For this, cellulases from alternative fungal and other microbial sources should be explored, particularly focusing on finding candidates that have higher specific activity and that are less susceptible to inhibition by glucose and lignin-derived compounds.

Agriculture

The applicability of fungal cellulases in agricultural biotechnology has also been explored. Supplementation of agricultural soil with cellulases has been reported to improve soil fertility by accelerating decomposition of plant residues in soil. For example, addition of commercial *T. reesei* cellulase to soil promoted degradation of rice and wheat straw as well as increased the amount of available nitrogen and phosphorous, and enhanced rice growth (Han and He, 2010). However, the use of cellulases to improve soil properties is not currently economically feasible. Other potential agricultural applications of cellulases include their use as biocontrol agents. *T. longibrachiatum* strains overexpressing an indigenous *egl1* gene have been studied as biocontrol agents against the oomycete *Phytophthora ultimum* that has cellulose as a major component of its cell walls. An increased EGL activity was reported to correlate with enhanced suppression of infection on cucumber seedlings (Migheli *et al.*, 1998).

Cellulases and other plant cell wall polysaccharides degrading enzymes can enhance the release and availability of bioactive compounds from plants by disrupting the structural integrity of the cell wall components. Therefore, enzyme-aided extraction provides a promising greener alternative by reducing the amount of chemicals and energy needed for the processing (Puri *et al.*,

2012). As an example, an *Trichoderma* spp. enzyme mixture containing cellulases and hemicellulases was shown to improve availability of phenolic compounds for subsequent methanol extraction from blackcurrant (*Ribes nigrum*) juice press residues (Kapasakalidis *et al.*, 2009). In addition, the use of the commercial cellulase mixture Celluclast 1.5 L (Novozymes A/S) from *T. reesei* together with the hemicellulose and pectinase mixture Peelzyme I (Novo Nordisk Ltd.) from *A. niger* and *T. reesei* enhanced recovery of polyphenols from rosemary (*Rosmarinus officinalis*) and sage (*Salvia officinalis*) by 100% and 20%, respectively (Weinberg *et al.*, 1999). However, as, e.g., side activities in commercial enzyme preparations can reduce the yield or negatively affect the properties of the bioactive compounds, more specific enzyme cocktails tailored towards different plant materials are needed to further improve the extraction processes (Puri *et al.*, 2012; Phitsuwan *et al.*, 2013).

Improvement of Fungal Cellulases and Their Production

Even though several fungi are capable of cellulase production, the enzyme yield and amount of individual cellulase components are often not satisfactory for the above-mentioned industrial applications. Improvements in cellulase yield as well as the ability to tailor suitable ratios of the enzymes of the cellulase complex produced by fungi for individual processes is therefore important. In order to overcome these bottlenecks, different molecular engineering techniques have been successfully applied, and some examples of these are given in this section.

Forward Genetics

Forward genetics approaches that have been applied to induce genetic variation in fungi and through this improve their cellulolytic properties include UV- and chemical mutagenesis as well as adaptive evolution. For example, the use of random UV-mutagenesis yielded the hyper-cellulolytic *T. reesei* RUT-C30 strain (Montenecourt and Eveleigh, 1979). This mutant and another hyper-cellulolytic mutant *T. reesei* SS-II used in industry have recently been genome sequenced to identify genetic variations that may be involved in the high production of cellulases and thus, could contribute for further strain engineering (Peterson and Nevalainen, 2012; Liu *et al.*, 2019a). Another example of strain improvement using a combination of UV- and chemical mutagenesis is *Penicillium janthinellum* NCIM 1171 that was treated with ethyl methyl sulfonate (EMS) followed by UV-irradiation and resulted in the mutant EU1 with increased hydrolysis of microcrystalline cellulose, Avicel (Adsul *et al.*, 2007). Spore suspension of *Aspergillus oryzae* NRRL 3484 was also subjected to combination of UV-irradiation followed by chemical treatment to improve cellulase biosynthesis. As a result, a hyper-production strain UNAC4 was obtained that showed a 4-fold increase in cellulase activity compared to the wild type strain on rice straw (El-Ghonemy *et al.*, 2014). Another approach utilizing only chemical mutagens, 1-methyl-3-nitro-1-nitrosoguanidine (MNNG) and ethidium bromide (EtBr), was used to improve cellulase activity of seven fungal strains isolated from soil. When the strains were exposed to sublethal concentrations of the mutagens for a prolonged period, stable mutants with improved cellulase production were obtained (Chand *et al.*, 2005).

An alternative approach to UV- and chemical mutagenesis is strain engineering by adaptive evolution that is based on the microorganisms' capability to adapt rapidly to various environmental conditions and enhance enzyme production (Schoustra *et al.*, 2009; Kutyna *et al.*, 2012). Based on this approach, an *A. niger* cellulase mutant was obtained resulting in a five times higher cellulose production than the parental strain (Patyshakuliyeva *et al.*, 2016). Transcriptomic analysis revealed that the expression of *noxR* encoding the regulatory subunit of the NADPH oxidase complex was reduced in the mutant compared to the parental strain. Subsequently, analysis of the *noxR* knockout strain showed the same phenotypic effect as observed for the adapted evolution mutant, confirming the role of *noxR* in cellulose degradation (Patyshakuliyeva *et al.*, 2016).

Protein Engineering

Other approaches to enhance cellulase activity include protein engineering by directed evolution, computer-guided rational and semi-rational methods, and adaptive evolution. Directed evolution is another random mutagenesis method, which requires multiple cycles of mutagenesis to generate a large library and subsequent high-throughput screening of the library for identification of the improved strains (Bornscheuer *et al.*, 2019). The rational approach creates a smaller mutant library, but is considered smarter as the design method is based on in-depth analysis of amino acid sequences and protein 3D structures, which reflects the desired enzymatic properties (Cheng *et al.*, 2015). On the other hand, the semi-rational design combines the benefits of directed evolution with computational analysis and suggests multiple, specific residues to be mutated based on prior knowledge on the structural function relationship to design "smart" libraries to engineer desired properties (Chica *et al.*, 2005). These directed evolution approaches have been utilized to improve the activity of EGLs (Liu *et al.*, 2013), CBHs (Liu *et al.*, 2014) and BGLs (Hardiman *et al.*, 2010). Even though these techniques seem to show promising results, a bottleneck is the limitation of the screening systems, where the capacity of a regular microtiter plate based screening is limited to the simultaneous screening of 10^3 – 10^4 variants (Longwell *et al.*, 2017).

Not only protein yield and enzymatic activity are desirable targets of improvement for industry, but also enzymes' thermostability and performance in non-conventional media. Methods like SCHEMA (structure-guided protein recombination) was successfully used to improve the thermostability of an EGL by 13°C without affecting activity (Heinzelman *et al.*, 2009; Morais *et al.*, 2016). In addition to thermostability, cellulase stability in non-conventional environments, e.g., in ionic liquids, seawater

with high salt concentration or organic solvents, is essential for their performance in various applications. An example of this are the ionic liquid tolerant cellulases from *T. reesei* improved via engineering of enzyme charge (Nordwald *et al.*, 2014).

Overexpression and Promoter Engineering

Homologous overexpression of *T. reesei* EGL was shown to significantly promote saccharification of pretreated corn cob residues, which was even more pronounced when both EGL and BGL were overexpressed (Qian *et al.*, 2017). In *Penicillium oxalicum*, overexpression of nine *bgl* genes resulted in enhanced BGL activity and hydrolysis efficiency (Yao *et al.*, 2016). On the other hand, cellulase encoding genes from different fungi can be identified, cloned and heterologously expressed in fungal hosts to get a better combination or synergism of the corresponding cellulases. For example, a heterologously expressed BGL encoding gene from *Penicillium decumbens* led to improved cellulase activity in *T. reesei* (Ma *et al.*, 2011). In addition, cellulases from *T. reesei* have been successfully produced in the filamentous ascomycete *Ashbya gossypii* (Ribeiro *et al.*, 2010, 2013).

Another molecular engineering technique applied to improve cellulase activity is promoter engineering. CBH1 of *T. reesei* is the major component of all secreted proteins by this species. Therefore, the CBH1 promoter has been widely used to induce hyperproduction of target proteins in *T. reesei*, including BGL that is present at very low levels in *T. reesei* cellulase cocktails (Ma *et al.*, 2011; Li *et al.*, 2017). To improve promoter efficiency, binding sites within the CBH1 promoter of *T. reesei* have been replaced with those of transcriptional activators (Zou *et al.*, 2012). When a fusion gene that consisted of *cbh1* from *T. reesei* and EGL encoding *e1* from the bacterium *Acidothermus cellulolyticus* was expressed under a control of this engineered promoter, higher enzyme activity was obtained.

Manipulation of Transcriptional Regulators

In filamentous fungi, the expression of cellulase genes is governed by several transcriptional factors (TFs) (Benocci *et al.*, 2017), thus making them attractive targets for molecular engineering to improve cellulase production. One possibility for TF manipulation is their constitutive expression. For example, the xylanase transcriptional activators Xyr1 and XLR-1 from *T. reesei* and *Neurospora crassa*, respectively, control the expression of cellulolytic and hemicellulolytic enzymes encoding genes, and heterologous expression of the constitutively active mutants of these TFs in *P. oxalicum* was shown to result in increased cellulase production in the host species (Xia *et al.*, 2019). Furthermore, a chimeric TF that contain the DNA binding domain of the cellulase transcriptional activator ClnB and the C-terminal sequence of the constitutively active mutant of the hemicellulolytic activator XlnR, was tested for cellulase production under non-inducing conditions in *P. oxalicum*. As a result, up to 7.3-fold higher cellulase activity was observed in the modified *P. oxalicum* strains compared to the parental strain (Gao *et al.*, 2017).

Increased production and activity of fungal cellulases can also be achieved through overexpression of TFs. When the XlnR encoding gene was overexpressed in the hyper-cellulolytic strain of *T. cellulolyticus*, enhancement of cellulolytic activity and expression of *cbh1* was observed (Okuda *et al.*, 2016). Simultaneous overexpression of two transcription activators, Xyr1 and Ace3, in *Trichoderma orientalis* EU7-22, was found to substantially improve the production of cellulases (Xue *et al.*, 2020). In addition, the overexpression of *xyr1* in *T. harzianum* resulted in increased hemicellulolytic activities and showed significantly improved saccharification of sugarcane bagasse (da Silva Delabona *et al.*, 2017).

Deletion or disruption of transcriptional repressors offers another strategy to improve cellulase production in fungi. A typical target for this is CreA/CRE1 that is the negative regulator of the universal carbon catabolite repression (CCR) regulatory system by which utilization of the energetically most favorable carbon sources is ensured (Benocci *et al.*, 2017). For example, deletion and truncation of *cre1* in *T. reesei* resulted in derepressed production of cellulases and xylanase (Nakari-Setälä *et al.*, 2009), and higher transcript and enzyme levels of cellulases and xylanase were detected after disruption of *creA* gene in *T. cellulolyticus* (Fujii *et al.*, 2009).

Epigenetic Engineering and CRISPR/Cas9

Another potential tool for industrial engineering is epigenetic engineering, which concerns the heritable changes in gene expression that do not involve changes in the underlying DNA sequences. Two levels of epigenetic regulation are DNA methylation and chromatin remodeling by histone modification (Waddington, 1942; Aghcheh and Kubicek, 2015). Even though there is no evidence for a regulatory role of DNA-methylation for *T. reesei*, some data is available on chromatin remodeling. While several approaches on remodeling of chromatin by transcriptional activators for improvement of cellulase expression have been discussed and several genes encoding chromatin remodeling enzymes have been identified in *T. reesei* (Gupta *et al.*, 2016; Mello-de-Sousa *et al.*, 2015), whether these genes could be improve cellulase production has not been tested yet.

Novel genome editing techniques, such as CRISPR/Cas9 (Clustered Regularly Interspaced Short Palindromic Repeats/CRISPR-associated protein-9 nuclease from *Streptococcus pyogenes*) (Doudna and Charpentier, 2014; Wang and Coleman, 2019), have already been developed for several cellulase-producing filamentous fungi, such as *A. niger* (Nødvig *et al.*, 2015), *T. reesei*, *Penicillium chrysogenum* (Pohl *et al.*, 2016), *N. crassa* (Matsu-ura *et al.*, 2015) and *Myceliophthora* sp. (Liu *et al.*, 2017; Liu *et al.*, 2019b). A gene encoding the negative regulator Cre1 has been deleted by CRISPR/Cas9 in the thermophilic species *Myceliophthora thermophila* and *Myceliophthora heterothallica* (Liu *et al.*, 2015). As a result, the deletion strains showed increased cellulase production and activities (Liu *et al.*, 2015). It is likely that there will be more examples of the use of the CRISPR technology to improve fungal cellulase production in near future.

Concluding Remarks

Fungal cellulases are important industrial enzymes that can be applied in various industrial sectors. Extensive research has concentrated on these enzymes already for decades, leading to, e.g., detailed mechanistic understanding of the action of hydrolytic cellulases (Igarashi *et al.*, 2011). However, the industrially produced cellulases originate from few fungal species and, considering that the estimated number of fungal species is between 2.2 and 3.8 million (Hawksworth and Lücking, 2017), only a very limited potential of fungal cellulases has been investigated. It is plausible to expect that efficient enzyme discovery approaches that take advantage of the ever-increasing big data together with new genome editing tools and synthetic biology approaches will provide opportunities to faster introduction of new cellulases to industrial processes and the use of tailor-made cellulases for highly specific applications.

Introduction

Over the last few decades, microbial enzymes have gained a central role in the degradation of complex plant cell wall components either for developing an eco-friendly industrial process or in generation of value-added products from plant biomass. After cellulose, hemicellulose is the most abundant structural polysaccharide in plant cell walls making approximately 30% of its dry weight and is a perpetual by-product of agro-industries and forestry. The classification of hemicelluloses is based on the predominant monomeric sugar present in the backbone of the polymer (Dekker and Richards, 1976). Prominent hemicelluloses include xylans, xyloglucan, mannans and glucomannans. Among them, xylan, consisting of repeating units of xylose sugar linked with β -1 $\rightarrow$ 4 linkages, is the most abundant making up 15%–50% of cell dry weight. Xylan is classified into different categories based on the groups attached with the side chains. Homoxylan consists of xylose monomers bound by β -1 $\rightarrow$ 4 or β -1 $\rightarrow$ 3 linkages while arabinoxylans, occurring in cereals, have arabinose attached to xylose at C-2 or C-3 position. In glucuronoxylans found in hardwoods, every 10th xylose moiety is linked with 4-O-methyl-D-glucuronic acid. Acetyl xylan, found in beechwood and birchwood xylan, contains acetyl groups attached to xylose monomers. These acetyl groups of xylan help the polymer resist alkaline extraction. The last category is arabinoglucuronoxylan which is commonly present in grass where arabinose and glucuronic acid are substituents in different positions (Naidu *et al.*, 2018).

Mannan consisting of repeating mannose residues, occurs as storage polymer in some seeds and also as structural component of the plant cell wall (Krska and Larsbrink, 2020; Jana and Kango, 2020). Owing to glucose and galactose substitution, they are classified as glucomannan, galactomannan and galactoglucomannan. The hardwood glucomannan and softwood glucomannan have mannose-to-glucose ratio as 2:1 and 3:1, respectively (Soni and Kango, 2013a). The diversity and complexity of hemicellulose structure necessitates action of a wide range of enzymes for their degradation.

Fungi are natural decomposers of wood and elaborate immense number of extracellular enzymes for degrading complex polymeric substrates including hemicellulases. Over the last few decades, xylanases and mannanases sourced from different fungi have found novel and interesting applications in various industrial processes. Some major applications include bioconversion of lignocelluloses into fermentable sugars, upgrading of animal feedstock, clarification of fruit juices and wine, and facilitation of bio-bleaching of pulp (Fig. 1). As per the specific need of different applications such as bio-bleaching, bio-refinery, bio-scouring, de-inking, feed upgradation etc., a number of alkali-stable, acid-stable and thermostable hemicellulases of fungal origin have been characterized. According to the Association of Manufacturers and Formulators of Enzyme Product (AMFEP 2009), 60% of all the industrial enzymes are sourced from about 25 fungal genera, mainly *Aspergillus*, *Trichoderma*, *Penicillium*, *Rhizopus*, and *Humicola* (Kango *et al.*, 2019).

Fig. 1 Different industrial applications of fungal hemicellulases.

Fig. 2 Different types of fungal hemicellulases. A. Hemicellulases for complete breakdown of xylan, B. Hemicellulases for complete breakdown of mannan.

Hemicellulases are named on the basis of corresponding substrate acted upon by them, e.g., endo-xylanase, β -xylosidase, acetyl xylan esterase, endo-mannanase etc. Among them, the endo-acting enzymes, such as endo β -1 $\rightarrow$ 4 xylanase or endo β -1 $\rightarrow$ 4 mannanase, hydrolyze the internal linkages of the glycosidic bonds and disrupt the macromolecular backbone (Fig. 2). Being heteropolymeric, different factors like length, branching and nature of substituents in the hemicellulose, determine the efficacy of the enzyme action. In some case, de-branching or side-chain cleaving enzymes (e.g., α -galactosidase) help to disintegrate the substituents resulting in better substrate accessibility, while some de-branching enzymes act on oligomers generated after the action of endo-acting enzymes and thus assist in complete degradation of hemicelluloses. The main action of subsidiary enzymes is to cleave the groups attached with the main chain of hemicellulose structure where they exhibit co-operativity in their action (Soni and Kango, 2013b; Mäkelä *et al.*, 2018). For example, complete degradation of a complex xylan (glucuronoarabinoxylan or galactoglucuronoarabinoxylan) requires the concerted action of endo-xylanase, β -xylosidase (EC 3.2.1.37), acetyl xylan esterase (EC 3.1.1.72), α -arabinofuranosidase (EC 3.2.1.55), ferulic acid esterase (EC 3.1.1.73), α -glucuronidase (EC 3.2.1.139), α -galactosidases (EC 3.2.1.23) and *p*-coumaric acid esterase (EC 3.1.1.73). Similarly, mannan hydrolysis requires β -mannosidase (EC 3.2.1.25), α -galactosidase (EC 3.2.1.22), β -glucosidase (EC 3.2.1.21) and acetylmannan esterase (EC 3.1.1.6) along with endo- β -mannanase (Fig. 2). Fungi are the most potent producers of extracellular lytic enzymes, including hemicellulases (Bhattacharya *et al.*, 2015). Interestingly, often a single fungus is found to produce a repertoire of hydrolases, including main chain hydrolyzing and accessory enzymes (Prajapati *et al.*, 2020). Multiplicity of endo-xylanases and endo-mannanases, seen in various fungi, suggests their versatility in degrading the hemicelluloses.

Fig. 3 In bio-bleaching, xylanase degrades xylan complex entrapped in the cellulosic fibers and enhances removal of chromophores.

Applications of Hemicellulases

Beginning with a technical application of xylanases in pulp and paper industry in bio-bleaching (Viikari *et al.*, 1994), fungal hemicellulases have found a number of applications in various industrial domains in the last three decades. Their hydrolytic activity is utilized either to remove or release unwanted xylan or mannan residues from plant biomass, poultry feed, dough, cotton etc. or to saccharify the hemicellulosic component for the release of monomeric sugars. The details of such applications are given in the following section.

Bio-Bleaching

In the kraft pulping process, pulp lignin is removed by a bleaching treatment leading to xylan precipitation on the outer surface of the cellulosic fibers (Fig. 3). Xylanases degrade the re-deposited xylan chromophores and enhance the bio-bleaching process (Suomäki *et al.*, 1997). Although bacterial xylanases offer some advantages over fungal xylanases due to their broad pH and temperature range, most of the commercial xylanases employed in the pulp industry are of fungal origin. Large scale production of thermostable fungal endo-xylanases to the level of 34.4 IU/g using *Aspergillus oryzae* has helped in making this choice (Chutani and Sharma, 2015). Different thermophilic fungal species *viz.* *Thermomyces lanuginosus*, *Humicola insolens*, *Malbranchea* sp., *Chaetomium thermophilum*, *Melanocarpus* sp. and *Thermoascus aurantiacus* are reported to produce thermostable endo-xylanases that may be exploited for bleaching process. In particular, thermostable cellulase-free endo-xylanase originating from *T. lanuginosus* has drawn considerable attention (Maijala *et al.*, 2012; Kumar *et al.*, 2016).

Xylanases are classified into glycosyl hydrolase (GH) families namely, GH8, GH10, GH11, GH12 and GH30, respectively (see “Relevant Websites section”). Endo-xylanases belonging to GH10 have better thermostability and high accessibility towards the xylan over GH11, which provides advantage in pulp bio-bleaching (Hu and Saddler, 2018). During the bleaching process or alkaline cooking, 4-O-methyl glucuronic acid present in xylan gets converted into hexenuronic acid which adds to the pulp yellowing necessitating its removal (Hutterer *et al.*, 2017). Endo-xylanases act on these brownish deposits and release xylan from cellulose fibers, thus leading to an increase in the whiteness of pulp. Endo-xylanase from *Penicillium oxalicum* has been shown to reduce the yellowing of wheat and poplar pulp (Zhang *et al.*, 2016). Another accessory enzyme, feruloyl esterase, augments the action of bio-bleaching xylanase by reducing the hindrance caused by side chains present in the polymer thus increasing the solubilization of lignocellulosic components (Dilokpimol *et al.*, 2016). For example, feruloyl esterases from *Aspergillus terreus* have been shown to have wide range of activity on different esters making them potentially suitable for application in pulp and paper industry (Mäkelä *et al.*, 2018).

Recycling of printed paper is one of the major steps to address the environmental concerns related to perpetual cutting of trees for pulp. Removal of ink from the printed paper, e.g., newspaper, is called deinking and is the most difficult step in achieving the paper recycling. A typical enzyme-based deinking process involves pulping of the waste paper by hydropulper followed by the addition of enzyme. Afterwards, the pulp is treated at 121°C for 15 min and then washed with excess of water to remove the ink residue. The release of ink is made easy by the degradation of hemicellulosic fibers by hemicellulases in the fibre-ink bonding region. Endo-xylanase treatment is an eco-friendly and effective intervention for removal of ink particles from the paper fibers replacing hazardous chemical treatment. The enzyme treatment is shown to cause reduction in effective residual ink concentration and kappa number while increasing the paper brightness. Treatment with cellulase reduces paper strength, while laccase causes yellowing of the paper and hence, endo-xylanase makes a suitable de-inking agent without compromising paper quality (Desai and Iyer, 2016). Endo-xylanases from fungi, namely *A. niger* (Desai and Iyer, 2016), *Trichoderma harzianum* (Pathak *et al.*, 2014), and *Trichoderma longibrachiatum* (Chutani and Sharma, 2016) are reported to be effective in deinking process. Often, the combinatorial approach involving cellulase, xylanase, amylase and lipase has been found more efficacious (Xu *et al.*, 2009; Dutt *et al.*, 2012). A crude endo-xylanase preparation from the basidiomycete, *Coprinopsis cinerea*, used for deinking also resulted in improved brightness (Dutt *et al.*, 2013).

Bio-Scouring

Cotton fiber, having multifarious applications, is the most valuable raw-material for the textile industry. Natural cotton has some hemicelluloses, lignin, fats, pectin, etc. as impurities. These impurities are removed by a pretreatment process consisting of three steps *viz.*, de-sizing, scouring and bleaching. In the scouring process, the removal of non-cellulosic substances clinging to the cellulosic fibers results in a softer and finer fabric (Fig. 3). Similar to the pulp treatment, conventional chemical treatments impart adverse effects on the fabric quality parameters such as fabric strength, tenacity and whiteness along with the eventual release of harmful chemicals in the environment. Endo-xylanase based bio-scouring is eco-friendly, energy saving and non-damaging to the cellulosic material. It is important to ensure that xylanase should be cellulase-free, so that the cotton polymer remains unaffected. Several fungal xylanases have been explored in the textile industry. Treatment of cellulosic fiber with endo-xylanase from *T. longibrachiatum* was shown to effectively improve bio-scouring, de-sizing and bio-finishing of the fiber without needing any additives (Abd El Aty *et al.*, 2018). In addition, combination with pectin degrading enzymes helped to improve cotton wetting ability and decreased the enzyme load in the treatment (Puranen *et al.*, 2014). In case of less fiber accessibility, EDTA is applied in the bio-scouring process because it modifies the internal structure of the polymer by removing calcium ions from pectin that reduces polysaccharide cross-bridges and steric hindrance for enzyme action. EDTA concentration is selected in such a way that it does not affect the main enzyme adversely (Choudhury, 2014).

Biorefining

The process by which different value-added products are obtained from valorization of biomass is termed as biorefining. Enormous amounts of lignocellulosic biomass generated as a waste or by-product of agro-industry, forestry etc. can serve as renewable bio-resource for generation of bioethanol, phenolics and fermentable simple sugars such as glucose and mannose (Den *et al.*, 2018). The hemicellulose portion of the lignocellulosic biomass can be degraded into simpler constituents and exploited using fungal hemicellulases. Agro-industrial waste products such as corn cob, sugarcane bagasse, copra meal, palm kernel cake and spent coffee grounds, contain high amount of hemicelluloses. In absence of appropriate technology, these are disposed instead of being valorized. Valorization of hemicelluloses usually involves two sequential steps. At first, the hemicellulose polymer is converted into simple monomeric sugars and next, these sugars are transformed into different value-added products. For example, xylan and mannan are hydrolyzed into xylose and mannose, respectively, and then further converted into bio-ethanol and xylitol using different biological or chemical methods (Table 1).

Pentose sugars present in hemicelluloses are not effectively utilized by the yeast *Saccharomyces cerevisiae*, which is routinely used for ethanol production at industrial level. Some other yeasts, however, are able to ferment xylose into xylitol through the enzymatic action of xylose reductase. Further, xylitol dehydrogenase converts this xylitol into xylulose, which is then fermented by the yeast into ethanol *via* pentose phosphate pathway (PPP) and glycolysis (Matsushika *et al.*, 2008). *Candida* spp. are natural D-xylose consumers and have more reduction oxidation balance during xylitol accumulation than *S. cerevisiae* (Morales-Rodriguez *et al.*, 2016). For example, sugarcane bagasse hydrolysate containing xylose was obtained from treatment with an *Aspergillus tubingensis* enzyme complex and it was converted into bio-ethanol using *Candida shehatae* (Prajapati *et al.*, 2020). One of the main problems for yeast cells is the presence of glucose repression and their sensitivity to high ethanol concentration. Yeast cells use Snf3/Rgt2 signaling pathway as a sensory cascade for detecting glucose level in the surrounding medium. The high glucose concentration controls the glucose uptake for maintaining the intracellular glucose homeostasis through this signaling pathway (Kayikci and Nielsen, 2015). Similarly, high ethanol produced in the medium inhibits the yeast growth and increases the cell death. High concentration of ethanol also influences the macromolecular biosynthesis, protein accumulation and functioning of glycolytic enzymes adversely (Stanley *et al.*, 2010).

An ascomycetous yeast, *Spathaspora passalidarum*, has been shown to ferment both xylose and glucose with high xylose fermentation efficiency due to allosteric activation of glycolysis and high affinity to NADH and xylose by xylose reductase (Long *et al.*, 2012). Similarly, some xylose fermenting white rot fungi such as *Peniophora cinerea* and *Trametes suaveolens* (Okamoto *et al.*, 2010), *Hohenbuehelia* sp. (Liang *et al.*, 2013) and *Schizophyllum commune* (Horisawa *et al.*, 2015) converted hemicellulose hydrolysate into bio-ethanol (Fig. 4).

Table 1 Fungal enzymes used in biorefinery industry and their final products

Substrate	Enzyme	Organism	Final product	Reference
Beechwood xylan and pretreated straw lignocelluloses	β -xylosidase, endo-1,4- β -xylanase	<i>Aspergillus niger</i>	Bioethanol	Boyce and Walsh (2018)
Wheat biomass	β -xylanase	<i>Fusarium</i> sp.	Bioethanol	Juodeikiene <i>et al.</i> (2012)
Wheat Straw	Spezyme (CP) containing xylanase	<i>Trichoderma reesei</i>	Xylitol	Liavoga <i>et al.</i> (2007)
Palm kernel cake	mannanase	–	Biobutanol	Shukor <i>et al.</i> (2016)
Wheat straw hydrolysate	–	<i>Aspergillus carbonarius</i>	Citric acid	Yang <i>et al.</i> (2016)

Fig. 4 Xylitol, mannitol and ethanol production from hemicelluloses (xylan and mannan) using fungal hemicellulases and yeasts in bio-refinery.

Table 2 Commercial hemicellulases used in juice industry and their fungal sources

Trade name	Manufacturer	Composition	Source
Pectinex Superpress	Novozymes	Pectin transesterase, polygalacturonase, pectin esterase, hemicellulases	<i>Aspergillus niger</i>
Pectinex Ultra SP-L	Novozymes	Pectolytic and hemicellulolytic enzymes	<i>Aspergillus aculeatus</i>
Rapidase BE Super	DSM Gist-Brocades Delft	Pectinases and hemicellulases	<i>A. niger</i>
Vinozyme G	Novozymes	Pectin lyase, polygalacturonase, hemicellulase and cellulase	<i>A. niger</i>
Cytolase 219	Danisco and Genencor	Pectinase, cellulase, hemicellulase	<i>A. niger</i> and <i>Trichoderma longibrachiatum</i>

Wine and Fruit Juice Clarification

In the wine and juice industry, hemicellulases such as xylanases and mannanases are mainly used for pigment extraction, minimizing haze formation, maceration of fruit skin, and overall clarification of wines and different fruit juices. Hemicellulases are used in these industries to obtain better juice quality and stability by decreasing the amount of crystallization of different carbohydrate macromolecules extracted from fruit cell walls (Beveridge and Wrolstad, 1997). In case of maceration of juice, macerating enzymes help liquefaction of fruit pulp and reduce the processing time. In addition, these enzymes also help to clarify the juice by lowering the juice viscosity (Sharma et al., 2017). Hemicellulases having acid-stable character are thus required for the process. An acid stable endo-xylanase from *Gloeophyllum trabeum* decreased the mash viscosity and improved the filtration rate (Wang et al., 2016a). Usually, the enzyme cocktails employed for wine and fruit juice clarification consist of pectinase blended with different hemicellulases, as they have been shown to be more efficient (Koffi et al., 1991) (Table 2). The commercially available enzyme cocktails such as Pectinex Superpress, Pectinex Ultra SP-L, Rapidase BE and Vinozyme G. Pectinex Ultra SP-L contain hemicellulases from *Aspergillus aculeatus* or *A. niger* (Landbo and Meyer, 2004). A cellulase-free endo-xylanase belonging to GH11 from *Fusarium* sp. was shown to be effective in clarifying orange juice (Li et al., 2020). A hemicellulolytic blend from *Aspergillus quadrilineatus* immobilized on aluminum oxide pellets has been shown to enhance quality of different fruit juices by reducing turbidity and improving sugar content (Suryawanshi et al., 2019). Similarly, an enzyme mixture containing endo-xylanase from *A. niger* immobilized on magnetic nanoparticles has been shown to clarify papaya juice and was reusable upto 3–4 cycles (Muley et al., 2018).

Oligosaccharide Generation

Due to increasing awareness regarding harmful effects of antibiotics and role of prebiotics in modulation of intestinal flora, recent years have witnessed a growing trend in the use of prebiotic oligosaccharides as nutraceuticals (Jana et al., 2021). Besides conventional prebiotics like fructooligosaccharides (FOS), oligosaccharides derived from lignocellulosic biomass are also looked upon as upcoming prebiotics. Among these, xylooligosaccharides (XOS) and mannoooligosaccharides (MOS) obtained from the enzymatic hydrolysis of xylan and mannans are receiving considerable attention (Suryawanshi and Kango, 2021). The controlled hydrolysis of lignocellulosic biomass using fungal hemicellulases allows the use of the agricultural waste for generation of value-added next generation prebiotic oligosaccharides (Table 3). Hemicellulases from *Trichoderma* and *Aspergillus* are being exploited for this purpose (Florescio et al., 2016). Thermophilic fungi produce thermostable enzymes that work efficiently at high temperatures thus help lowering chances of contamination. Different thermophilic fungi such as, *Myceliophthora heterothallica* (de Oliveira Simoes et al., 2019), *T. lanuginosus* (Shi et al., 2019), *Mycothermus thermophilus* (Ma et al., 2017) and *Thermobifida fusca* (Wang et al., 2015) have been shown to produce thermostable endo-xylanases, while *P. oxalicum* is reported to produce a thermostable endo- β -mannanase (Liao et al., 2014). Interestingly, in many cases, end products generated by the fungal hemicellulase action are very well defined. Endo-xylanase from *A. flavus* liberated only xylobiose and xylopentose from beechwood xylan (Chen et al., 2019). Similarly, *Kitospora* sp. endo-xylanase generated only xylooligosaccharides from bagasse without any xylose formation (Rahmani et al., 2019). *A. terreus* endo- β -mannanase hydrolyzed locust bean galactomannan (LBG), guar galactomannan (GG) and konjac glucomannan (KG) with mannotriose as the predominant oligosaccharide in case of LBG and GG, while mannotetraose was the prominent oligosaccharide generated from KG (Soni et al., 2016). A multi-tolerant endo- β -mannanase from a well-known GRAS fungus, *Aspergillus oryzae* was able to hydrolyze different mannans into mannoooligosaccharides (Jana et al., 2018). Three endo-xylanases from *Penicillium chrysogenum* worked in a synergistic manner and produced XOS having different degree of polymerization (DP) (Yang et al., 2019).

Guar gum is obtained from *Cyamopsis tetragonolobus*, a legume, grown mainly in India (80% of the total production) and some Asian countries (Yoon et al., 2008). Fungal endo-mannanases hydrolyze guar gum into partially hydrolyzed guar gum (PHGG) that is heat tolerant, water soluble, acid-stable and taste-free dietary fiber (Niv et al., 2016). PHGG consumption has been shown to alter bowel microflora favorably in animals and humans, and confer beneficial effects in treatment of irritable bowel syndrome, relief in constipation, and stimulation of growth of probiotic bacteria (Mudgil et al., 2014). PHGG supplementation brings about significant increase in the population of probiotic bacteria, *Bifidobacterium* and *Lactobacillus* (Tuohy et al., 2001). Guar gum contains about 38% galactose and thus its effective hydrolysis necessitates α -galactosidase activity. *P. oxalicum* produced both endo- β -mannanase and

	<i>Penicillium freii</i>	4.5	4.0–12.0	Wang <i>et al.</i> (2012)

α -galactosidase, and generated DP 2–7 mannoooligosaccharides from guar galactomannan (Kurakake *et al.*, 2006). The formation of MOS (M3, M4) and PHGG using *A. oryzae* endo- β -mannanase has been demonstrated from guar gum (Jana *et al.*, 2018). PHGG contains higher molecular weight mannoooligosaccharides and is reported to confer physiological health benefits. An endo- β -mannanase from *Rhizomucor miehei* generated PHGG at higher rates yielding 90.6% of total dietary fiber (Li *et al.*, 2017).

Detergent Additives

Easy and quick cleaning of the sticky organic dirt from clothes and dishes without using harmful chemicals is very challenging. Different stains arising from tomato sauce, coffee and tea usually contain hemicelluloses, especially mannan. Mannans are used as thickeners in various foods and due to their gelling nature the food dirt acquires very sticky nature and is very hard to clean from clothes and utensils. Fungal mannanases degrade the mannan content of the organic dirt and thus enhance the detergents' cleaning performance. Detergents are alkaline in nature and hence it is desirable to use alkali-stable mannanases. Alkaliphilic microorganisms are one of the major sources of alkali stable enzymes, however, some mesophilic microorganisms are also reported to produce alkali-stable hemicellulases (Table 4). Fungal species like *R. miehei* (Katrolia *et al.*, 2013), *Penicillium freii* (Wang *et al.*, 2012), *H. insolens* (Luo *et al.*, 2012) and *Bispora antennata* (Liu *et al.*, 2012) are known to produce alkaline endo-mannanase. Consequently, other alkaline active enzymes such as cellulases, amylases and xylanases can also be used with mannanases for better performance in washing.

Bakery

In the bakery industry, xylanases are used to enhance the dough specific volume, elasticity, water absorption, and improve the extensibility, softness and chewiness of the product. Xylanases which have capability to solubilize the water insoluble wheat

arabinoxylan are the most advantageous for dough treatment. Treatment of dough with endo-xylanase from *Penicillium citrinum* liberated xylan and created a continuous gluten network and the large starch molecules were found absorbed on the evenly distributed protein network (Ghoshal *et al.*, 2017). Sometimes, combination of different enzymes, including endo-glucanase, phytase, amylase and protease is applied together with endo-xylanase for achieving better dough performance. Commercial xylanase powder (Pentopan Mono BG[®]) from *A. oryzae* when administered with amylase and cellulase, increased dough stability, extensibility and stickiness (Liu *et al.*, 2017). A commercial thermostable endo-xylanase from *T. lanuginosus*, Novozyme 899, is widely used in baking industry to improve the crumb structure and dough stability (Chadha *et al.*, 2019). Endo-xylanase from *Myceliophthora thermophila* (previous name *Sporotrichum thermophile*) helped to increase the concentration of various metal ions in the bread dough (Bala and Singh, 2017). Similarly, endo-xylanase from *Chaetomium* sp. improved specific volume of Chinese steamed bread along with decreased crumb firmness and spread ratio (Jiang *et al.*, 2010). In addition, hardness and chewiness of Chinese steamed bread dough decreased after treatment with endo-xylanase from a salt-tolerant mangrove-isolated fungus, *Phoma* sp. (Wu *et al.*, 2018).

Animal Feed Up-Gradation

The animal feed industry is one of the fastest growing industries with an annual turnover of over USD 400 billion (see “Relevant Websites section”). Use of fungal enzymes in this industry for feed up-gradation has a well-grounded future. Animal feed contain raw cereal grains which have significant amounts of arabinoxylan and mannan as part of endosperm cell wall. These polymers impart anti-nutritional properties as they increase the viscosity of the feed and result in its low mobility in the digestive tract and colonization of pathogenic bacteria. Hemicellulose degrading enzymes are not secreted by the animals’ digestive system and hence extraneous addition of fungal xylanases and mannanases helps in reducing the feed viscosity leading to improved mobility, digestion and animal growth. At the same time, the hemicellulase treatment hydrolyzes the otherwise indigestible hemicellulose fraction of animal feed into short chain carbohydrate oligomers that enhance the growth of beneficial microbes in the gut. Acid stable fungal hemicellulases are more suitable for such applications as they perform better in the acidic condition prevalent in the digestive tract. Some acid stable endo-xylanases have been reported from *Penicillium sclerotiorum* (Knob and Carmona, 2010), *Bispora* sp. (Luo *et al.*, 2009a), *Phialophora* sp. (Zhang *et al.*, 2011) and *Aspergillus sulphureus* (Yang *et al.*, 2017). Similarly, acid stable endo-mannanases are reported from *Bispora* sp. (Luo *et al.*, 2009b), *Phialophora* sp. (Zhao *et al.*, 2010), *Penicillium pinophilum* (Cai *et al.*, 2011), *B. antennata* (Liu *et al.*, 2012), *A. niger* (Sornlake *et al.*, 2013), *G. trabeum* (Wang *et al.*, 2016b) and *Aspergillus kawachii* (Liu *et al.*, 2020). One of the commercially available heat stable commercial enzymes used in feed treatment is Ronozyme WX CT (endo-xylanase) which is derived from thermophilic *T. lanuginosus* (Nielsen *et al.*, 2008).

Conclusions and Future Perspectives

Hemicellulases, such as xylanases and mannanases, have gained importance as they have become an integral part of several commercial products such as detergents and feed additives, and industrial applications such as bio-bleaching, bio-scouring, paper deinking and prebiotic oligosaccharide generation. Fungi, being natural plant biomass decomposers, possess a variety of endo-xylanases and endo-mannanases along with accessory enzymes. The desirability of obtaining thermostable and alkali stable hemicellulases in larger amounts has triggered search for novel fungal sources and optimized production methods. Fungal hemicellulases hold a great promise in valorization of large pool of plant biomass and agro-industrial wastes like palm kernel cake, copra meal, and corn cobs for generation of value-added products like oligosaccharides, alcohols and, readily fermentable simple sugars (mannose, xylose).

Introduction

Enzymes that degrade the plant cell wall (PCW) have been extensively studied because of their central role in the plant-pathogen interaction. However, the production, properties and applications of these enzymes has gained enormous interest as a result of well-documented biotechnological potential (Lara-Márquez *et al.*, 2011; Edwards and Doran-Peterson, 2012; Latarullo *et al.*, 2016; Troiano *et al.*, 2020). Particularly, fungi well-known as producers of lytic enzymes such as pectinases, hemicellulases, and cellulases, have been widely studied because to the advantages of these organisms as models and the inherent characteristics of their lytic systems (Conejo-Saucedo *et al.*, 2010; Lara-Márquez *et al.*, 2011; Troiano *et al.*, 2020). The demand for such enzymes and their application in various industrial processes is largely due to their high efficiency in removing PCW components and their environmental benefits. Some of the advantages of fungi to produce these enzymes include their fermentation capacity, the production of large amounts of extracellular enzymes, the ease of cultivation, and the low cost of enzyme production in bioreactors (de Vries and Visser, 2001; Lara-Márquez *et al.*, 2011). In this context, most commonly used fungi are species and strains of the *Aspergillus* genus though other fungi have also been proven as efficient enzyme producers (Belda *et al.*, 2016; de Vries *et al.*, 2017; Amin *et al.*, 2019). Among these enzymes, pectinases are widely used in industrial applications such as fruit juice and wine clarification, tea and coffee fermentation, cotton bio-scouring, degumming of plant fibers, oil extraction, biofuel production, treatment of industrial wastewaters containing pectin, and synthesis of a number of value-added products (Edwards and Doran-Peterson, 2012; Kohli and Gupta, 2015; Amin *et al.*, 2019). Here we review the applications of pectinolytic enzymes produced by filamentous fungi and the strategies for their application and improvement of industrial processes.

Pectin Structure and Depolymerization

Pectin is the main component of the middle lamella of the PCW, where it is involved in functions such as adhesion between cells with active division (cell expansion), morphogenesis, porosity, ion binding, pH and ion balance, seed hydration, leaf abscission, fruit development, defense, among others (Mohnen, 2008; Lara-Márquez *et al.*, 2011). The pectin content of plant cell walls varies between dicots and nongraminaceous monocots (30%–35% dry weight [dw]), monocots such as grasses (2%–10% dw), and wood (5% dw), and different plant tissues depending of their function and stage of development (Mohnen, 2008; Voragen *et al.*, 2009). In immature fruits, insoluble pectin binds to cellulose resulting in stiffening of the cell wall. Later, during the ripening pectin is modified by plant pectinases, which soften the cell wall (Kashyap *et al.*, 2001). Pectin represents a large part of the biomass in ripe fruits and vegetables (>30%) (Hoondal *et al.*, 2002).

Pectin is mainly composed of homogalacturonan (HG; ~65%) followed by domains of xylogalacturonan (XGA; 20%–35%), and in minor proportion (~10%) rhamnogalacturonan I (RG-I) and rhamnogalacturonan II (RG-II) (Mohnen, 2008). HG is a domain of approximately 100 galacturonic acid residues (GalA) with α -1,4 bonds, methyl-esterifications at C-6, or acetyl-esterification at O-2 and O-3 (Mohnen, 2008). XGA is a HG backbone with 25%–75% of the GalA units substituted at C-3 with xylose and occasionally at C-4 with a second xylose residue (Mohnen, 2008). RG-I, is a heteropolymer consisting of α -D-GalA-1,2- α -L-Rha-1,4- disaccharide units, whose GalA residues can be highly acetylated in O-2 and/or O-3, and with 20%–80% of the rhamnose (Rha) residues substituted with chains of arabinose and galactose of variable size, and occasionally with chains of fucose and glucuronic acid (Mohnen, 2008). RG-II consists of a main chain of HG with side chains formed by around 12 different sugars (arabinose, galactose, xylose, fucose, aceric acid, glucuronic acid, apiose, etc.) (Mohnen, 2008). The structural domains of pectin interact between themselves and with other molecules such as calcium, borate, polyamines, phenolic compounds, hemicellulose and cellulose (Popper and Fry, 2008).

The degree of pectin esterification can be low (<50%), medium/partial (50%–70%) and high (>70%), depending on the origin, growth and maturity stage of fruits, vegetables or tissues (Ralet *et al.*, 2003). Polysaccharides of highly-esterified pectin establish weak interactions by hydrogen bonds and hydrophobic forces through methyl groups, whereas low-esterified pectin

Table 1 CAZy families to which fungal pectinases belong

Enzyme	E.C. number	CAZy Family
PGA	3.2.1.15	GH28
PGX	3.2.1.67	GH28, GH4
PLY	4.2.2.2	PL1, PL2, PL3, PL9, PL10
	4.2.2.9	
PEL	4.2.2.10	PL1
PME	3.1.1.11	CE8
RGAE	3.1.1. —	CE12
FAE	3.1.1.73	CE1/unclassified
RHG	3.2.1.171	GH28
RGX	3.2.1.173	GH28
RGL	4.2.2.23	PL4, PL9, PL11, PL26
RHA	3.2.1.174	GH78
GAL	3.2.1.89	GH53
	3.2.1.164	GH5, GH30
XGL	3.2.1.145	GH43
LAC	3.2.1.22	GH2, GH35
	3.2.1.23	GH42
ABF	3.2.1.55	GH2, GH51, GH43, GH62, GH2
ABN	3.2.1.99	GH43
ABX	3.2.1. —	GH93

PGA, Endo-polygalacturonase; PGX, Exo-polygalacturonase; PLY, Pectate lyase; PEL, Pectin lyase; PME, Pectin methyl esterase; AE, Acetylcysteine; RGAE, Rhamnogalacturonan acetyltransferase; FAE, Feruloyl esterase; RHG, Rhamnogalacturonan hydrolase; RGX, Rhamnogalacturonan galacturonohydrolase/exorhamnogalacturonase; RGL, Rhamnogalacturonan lyase; RHA, Rhamnogalacturonan rhamnohydrolase/ α -rhamnosidase; GAL, Endogalactanase; XGL, Exogalactanase; LAC, α - and β -galactosidases; ABF, α -L-arabinofuranosidase; ABN, Endoarabinanase; ABX, Exoarabinanase.

makes bonds between calcium and free carboxyl groups (Willats *et al.*, 2006). When HG polymers link to each other, pectin forms a gel with a crystalline network that traps water depending on factors such as temperature, degree of methyl-esterification and acetylation, pH, sugar and calcium concentrations (Willats *et al.*, 2006).

Pectin degradation depends on several carbohydrate active enzymes (CAZymes) belonging to different glycoside hydrolase (GH), polysaccharide lyase (PL), and carbohydrate esterase (CE) families of the CAZy database (See Relevant Website Section) (Table 1). Polygalacturonases (PGs) break glycosidic bonds between GalA residues and are classified as endo-PG (PGA) and exo-PG (PGX) (Fig. 1(A)) (de Vries and Visser, 2001). Pectate lyases (PLYs) and pectin lyases (PELs) degrade polygalacturonate and esterified pectin from HG, respectively, through β -elimination at the non-reducing end of pectin (Fig. 1(A)). PLY activity is specific for non-esterified pectin and Ca^{2+} -dependent whereas PEL activity is specific for methyl-esterified pectin and Ca^{2+} -independent. Arg^{236} in PEL seems to play a similar role as Ca^{2+} (Jayani *et al.*, 2005). The acetyl, methyl and feruloyl residues of the pectin are removed by pectin methylesterases (PMEs), acetyltransferases (AEs), rhamnogalacturonan acetyltransferases (RGAEs), and feruloyl esterases (FAEs) (Table 1, Fig. 1(A)). It is known that the efficiency of the degradation of pectin by PGs and PLYs is largely dependent on the activity of PMEs (de Vries and Visser, 2001).

The rhamnogalacturonan hydrolase (RHG) break the α -D-GalA-1,2- α -L-Rha bonds in RG-I, while rhamnogalacturonan lyase (RGL) degrades α -L-Rha-1,4- α -D-GalA bonds in RG-I (Fig. 1(B)). Rhamnogalacturonan rhamnohydrolase/ α -rhamnosidase (RHA) and rhamnogalacturonan galacturonohydrolase/exorhamnogalacturonase (RGX) break the α -D-GalA-1,2- α -L-Rha bonds in rhamnogalacturonan oligosaccharides from the nonreducing end (Fig. 1(B)) (de Vries and Visser, 2001).

Accessory enzymes acting on the side chains of RG-I and RG-II include endogalactanases (GALs), exogalactanases (XGLs), α - and β -galactosidases (LACs), α -L-arabinofuranosidases (ABFs), endoarabinanases (ABNs), and exoarabinanases (ABXs) (Table 1, Fig. 1(A)) (de Vries and Visser, 2001; de Vries, 2003).

Pectinase Production

Fungi produce pectinolytic enzymes for diverse purposes. The differences in enzyme production and specialization in depolymerization of substrates could be influenced by fungal lifestyle, environment and host. For instance, phytopathogenic fungi secrete pectinases during plant infection to overcome the PCW, the principal barrier for infection and invasion of host tissues. In fact, polygalacturonases are considered as virulence factors (Nakajima and Akutsu, 2014; Villa-Rivera *et al.*, 2017).

Saprotrophic fungal strains with pectinolytic capacity have been isolated from a variety of environments rich in lignocellulosic biomass such as forest soils (Banakar and Basaiah, 2012), municipal wastes (Banu *et al.*, 2010), agricultural waste, leaf litter,

Fig. 1 Structure of pectin and sites of attack by pectinolytic enzymes. (A) pectinases that degrade homogalacturonan (HG) backbone and rhamnogalacturonan II (RG-II) side chains. PGA: Endo-polygalacturonase; PLY: Pectate lyase; PME: Pectin methyl esterase; PEL: Pectin lyase; AE: Acetylesterase. (B) pectinases that degrade rhamnogalacturonan I (RG-I). RGX: Rhamnogalacturonan galacturonohydrolase/exorhamnogalacturonase; RHG: Rhamnogalacturonan hydrolase; RGAE: Rhamnogalacturonan acetylesterase; RGL: Rhamnogalacturonan lyase; RHA: Rhamnogalacturonan rhamnohydrolase/ α -rhamnosidase. Adapted from Mohnen, D., 2008. Pectin structure and biosynthesis. *Current Opinion in Plant Biology* 11, 266–277.

farmyard manure and cow dung (Anisa *et al.*, 2013), composts (Handa *et al.*, 2016), and decomposing fruits (Barman *et al.*, 2015; Amilia *et al.*, 2017). A wide variety of agro-industrial wastes that results from citrus fruit processing and pollute the environment, have been used as substrate for cheap pectinase production at large scale. These residues are easily accessible, have a low cost and their degradation constitutes an ecofriendly method that generate diverse monomers useful for different biotechnological purposes, thus contributing to reduce waste accumulation and pollution (Amin *et al.*, 2019).

Species of *Aspergillus* have been exploited commercially and are considered the principal hemicellulase and pectinase producers (Amin *et al.*, 2019; Troiano *et al.*, 2020). Due to wide biotechnological uses of these enzymes, new fungal strains able to produce higher pectinase amounts are explored. Also, recent efforts are focused on the improvement of fermentation conditions for increasing fungal growth and pectinase production. Accordingly, the amount of substrate, nitrogen and carbon sources, particle size of substrate, temperature, pH, inoculum size, mixing frequency, and time of incubation are among the factors evaluated (Table 2) (Amin *et al.*, 2019).

A diversity of pectin-containing agro-wastes such as groundnut oil, mustard oil, neem oil, black and green gram peels, wheat bran, finger millet waste, pearl millet residues, broken rice, banana peels, apple pomace, orange and lemon peels or mixtures of them have been tested as carbon sources for fungi (Table 2). Peels of fruits have been shown to be the best substrate for pectinase production due to their high pectin content. Moreover, addition of pectin to mixtures of natural substrates such as wheat bran + potato starch, or wheat straw + extracts of mosabi, orange, and lemon peels, remarkably increases pectinase production by *Aspergillus niger* (Akhter *et al.*, 2011; Khan *et al.*, 2012). Finally, it has been demonstrated that a pretreatment of orange peels using microwave and surfactants enhance the production of extracellular enzymes including pectinases in *Aspergillus japonicus* (Li *et al.*, 2015c).

Improvement of fermentation media for optimum pectinase production have been carried out in several fungal species and strains (Table 2). Solid and submerged state of fermentation have been tested with good results; conveniently, it has been reported that solid state fermentation could be less affected by catabolic repression than submerged cultures, and therefore produce higher amounts of pectinase (Sandhya and Kurup, 2013). A strategy implemented to decrease glucose content in the medium and therefore minimize catabolic repression was to co-culture *A. niger* GJ-2 with *Saccharomyces cerevisiae*, yielding a considerable increase of PG activity (Zhou *et al.*, 2011). The statistical Response Surface Methodology (RSM) approach applied in optimization of *Penicillium oxalicum* pectinase production using citrus peel in submerged fermentation, showed that temperatures of 35–39°C had more influence than NH_4Cl concentration (0.5–1.5 g l⁻¹) in enzyme production (Li *et al.*, 2015b). RSM application in *Aspergillus ibericus* pectinase production using citrus peel in submerged fermentation, showed a relationship between substrate concentration, temperature, pH, and incubation time for the optimal production of enzyme. After, immobilized purified fungal pectinase on functionalized nanoporous activated carbon, with a maximum immobilization capacity of 3360 U g⁻¹, showed

Table 2 Fermentation conditions for fungal pectinase production

Species	Enzyme	Medium	Carbon source	Nitrogen source	Yield	Temperature (°C)	pH	Time of incubation	Reference

better thermal and storage stability than free pectinase (Mahesh *et al.*, 2016). Also, nylon scouring pad cubes have been used as a matrix of support for immobilization of *A. niger* HFD5A-1 cells, increasing pectinase production to about 335% in submerged fermentation systems (Ibrahim *et al.*, 2014). Another strategy to increase PG activity in *Aspergillus sojae*, was the addition of 20 g l⁻¹ of aluminum oxide microparticles to shake flask fermentation medium, resulting in 2.2-fold higher levels of activity than control, a result that could be important to pectinase production in large scale bioreactors (Karahalli *et al.*, 2017).

Improvement of a medium for solid state of fermentation consist in the use of a column-tray bioreactor containing 70% of moisture and substrate particle size of 0.7–2 mm. When implemented in *Aspergillus* and *Penicillium* strains, this process resulted in high levels of fungal biomass and pectinase production (Ruiz *et al.*, 2012). On the other hand, a pilot scale packed bed bioreactor with up 30 kg of dry sugarcane bagasse was implemented in *A. niger* CH4 solid state fermentation, and may represent a low cost alternative for pectinase production (Pitol *et al.*, 2016). Finally, it has been reported that the implementation of intermittent agitation provide uniformity across the packed bed bioreactors, increasing pectinase production in solid state fermentation (Finkler *et al.*, 2017).

As pectinases have important industrial applications, they have been purified and characterized from native or heterologous systems. Some of their biochemical properties are summarized in Table 3, where it can be seen that molecular mass, optimum pH and temperature of characterized pectinases are very variable. Thermostable and thermophilic enzymes typically are the most useful for industrial applications. However, there are applications where low temperatures favor the quality of the final product. Additionally, the use of active enzymes at low temperatures eliminate the need to heat the system and decrease the energy required (Adapa *et al.*, 2014; Li *et al.*, 2017). Therefore, fungi capable of producing these types of enzymes are constantly being sought for use in biotechnological processes.

Biotechnological Applications

Juice Production

The viscosity in ripe fruits is a problem that hinders the filtration process producing a low yield and retention of molecules and pigments that contributes to the flavor and properties of juices (Adapa *et al.*, 2014). Juice extraction produces suspended insoluble particles formed by negatively charged pectin associated with proteins that prevents their precipitation (García, 2018). Filtration, decantation and centrifugation methods are common practices used for clearing or depectinization of juice extracts (Domingues *et al.*, 2012; García, 2018). However, the application of pectinases improves the quantity of the extracted juice, releases positively charged molecules, which aggregate and precipitate, makes liquefaction more efficient, increases the amount of soluble solids, reduces viscosity, facilitates filtration and clarification, increases acidity (citric acid) and the mount of anthocyanin and total

Table 4 Effects of pectinase treatment of some fruit juice extracts

Fruit	Fungus	Enzyme	Application effect	Reference
Apple	<i>Aspergillus awamori</i>	PGX	93% increased transmittance 38% viscosity reduction	Dey and Banerjee (2014)

carbohydrates, and increases color intensity and phenolic content (Sharma *et al.*, 2017; García, 2018). Then, the combined use of enzymatic degradation and filtration or centrifugation methods is a useful common practice (Sharma *et al.*, 2017; García, 2018). Some effects of pectinase addition to juice extracts such as change in clarity, viscosity, and turbidity are shown in Table 4. Juice fruits with high soluble pectin content such as banana or papaya are difficult to press, so the use of pectinases decreases viscosity and allows pressing and obtention of a better amount of juice (Garg *et al.*, 2016). In cases such as bitter gourd juice, which is considered medicinal with anticancer, antidiabetic, antimalarial, and anti-inflammatory properties, incubation with *A. niger* pectinases increases the amount of juice, allow the release of bioactive molecules such as phenolics, vitamins, minerals, α -amylase and α -glucosidase inhibitors (considered as antidiabetic), important for medicinal action (Deshaware *et al.*, 2017).

Wine Production

Pectinases can be used in several steps of the wine production process, for instance, addition to the pulp after fruit trituration, and before and after fermentation. Commonly, enzymatic preparations containing pectinases and cellulases known as liquefaction mixtures are added to the pulp, where they contribute to the degradation of plant tissue, the breakdown of the cell wall, and the release of pigments and phenolics from the grape skin (Sieiro *et al.*, 2012; Nighojkar *et al.*, 2019). Before and during fermentation pectinases allow sedimentation of suspended particles resulting in more clear wines, and their application after fermentation promotes flocculation and precipitation of pectin particles, microorganisms, and proteins (Nighojkar *et al.*, 2019). Addition of enzymatic mixtures during wine production also improve characteristics such as the presence of phenolic components, anthocyanins, catechin, color intensification and stabilization, aroma etc. (Sieiro *et al.*, 2012).

Olive Oil Extraction

Pectinases and other PCW degrading enzymes can increase oil production from olives and improve its organoleptic characteristics (Hadj-Taieb *et al.*, 2012). In olives, which have high content of pectin and hemicellulose, the use of enzymatic preparations of *Penicillium occitanis* with pectinase activity, and enzymatic extracts from *Trichoderma* sp. with cellulase and xylanase activities render good results. Enzymatic treatment increases the amount of olive oil extracted by 1.5%; moreover, the synergistic effect of cellulase, xylanase, and pectinase activities increase the content of polyphenols and pigments (Hadj-Taieb *et al.*, 2012). Similarly, the use of

an extract with pectinolytic activity from *Aspergillus giganteus*, increases the extraction of olive oil by 15.3%, and decreases viscosity and turbidity (70%) (Ortiz *et al.*, 2017).

Tea and Coffee Production

Typically, tea production uses mechanical maceration, but partial breaking of the cells in leaves can result in low quality tea. Pectinase treatment improves the characteristics of tea, because degradation of pectin improves the release of important components such as theaflavin, thearubigen, and caffeine (Murugesan *et al.*, 2002). When applied to the tea maceration process, raw pectinase extracts obtained from *Aspergillus indicus*, *Aspergillus flavus*, and *Aspergillus niveusdurante*, increase its quality by 5% (Angayarkanni *et al.*, 2002). The pectinases from *A. niger* and *Mucor circinelloides* used in the tea fermentation process increase the amount of phenolic compounds and quality of the beverage (Thakur and Gupta, 2012).

Coffee production uses a fermentation process to remove the mucilage layer of the internal mesocarp, which may contain up to 2.8% pectin. The use of *A. niger* pectinases reduces the process time, while maintaining grain quality (Murthy and Naidu, 2011).

Extraction of Phytopigments

Some analyses have shown that the use of commercial mixtures of pectinesterase, polygalacturonase, and pectin lyase from *A. niger* in the degradation of plant tissues improves the pigment extraction and avoids oxidation (Çinar, 2005). In addition, mixtures of cellulase and pectinase have been used for the extraction of carotenoids from orange peel, sweet potato, carrot, red capsicum and pumpkin, among others (Çinar, 2005; Nath *et al.*, 2016). Pectinases have also been used to obtain tomato lycopene, a high-value carotenoid for the pharmaceutical, cosmetic and food industry (Choudhari and Ananthanarayan, 2007), as well as for the extraction of antioxidant phenols and anthocyanins from black currant juice press residues (Landbo and Meyer, 2001). Recently, the use of *Aspergillus tamarii* pectinases for the production of lycopene and anthocyanins from agro-industrial waste has been reported (Shanmugavel *et al.*, 2018).

Bio-Scouring of Cotton

The cotton fiber used in the textile industry contains about 10%–12% of pollutant material, such as lipids, pectin, organic acids, proteins, etc. Since these molecules affect the characteristics of the cloth, they are removed with highly polluting alkaline washes (Hartzell and Hsieh, 2016). Alternatively, the bio-scouring process of cotton fiber and other fibers used in textile manufacturing, with mixtures of lytic enzymes is used to remove all non-cellulosic components, with low energy consumption and highly reduced pollution (Garg *et al.*, 2016). Typically, the bio-scouring process is carried out using mixtures of pectinases and cellulases, or only pectinases. Alkaline pectinase is the most suitable enzyme to produce better cloth characteristics, such as absorption, whiteness, higher tenacity and hydrophilicity (Besegatto *et al.*, 2018). On the other hand, the use of acidic and neutral pectinases are alternatives to chemical treatment due to ecological benefits, since it is not necessary to neutralize the wastes (Pušić *et al.*, 2015).

Commonly, fungal pectinases from *Penicillium italicum*, *Aspergillus fumigatus*, and *Fusarium* sp., among others, are used in the bio-scouring processes (Baracat-Pereira *et al.*, 1993; Brühlmann, 1995; Beg *et al.*, 2000).

Biofuel Production

The use of agricultural and forestry wastes as sources of simple sugars for fermentation, is an alternative in the production of bioethanol, instead of the sugar cane and corn currently used (Zhao *et al.*, 2012). In the process of bioethanol production, complex biomass such as lignocellulose is pre-treated for a more efficient digestion, allowing a better enzymatic conversion of polysaccharides into monomeric sugars whose fermentation by yeast produces bioethanol (Jørgensen *et al.*, 2007). It is believed that pectinase treatment is not fundamental in lignocellulose saccharification, since the pectin content is low in lignocellulosic tissues such as agricultural and forestry wastes. However, pectin can play a role as a binder and its function in the middle lamella as an adhesive and porosity regulator can interfere with the hydrolysis of the other polymers and the release of sugars (Jarvis *et al.*, 2003; Xiao and Anderson, 2013; Latarullo *et al.*, 2016).

Despite of being an attractive alternative to the use of corn grains or lignocellulose for bioethanol obtention, pectin rich (12%–35% dw) agro-industrial wastes such as sugar beet pulp, citrus waste and apple pomace, among others, are rarely used. These wastes from the food industry are advantageous as they are cheap and the partially degraded biomass does not require a special treatment prior to enzymatic degradation (Edwards and Doran-Peterson, 2012).

Direct fermentation of sugars produced by saccharification of lignocellulose represents an excellent alternative, but yeasts such as *S. cerevisiae*, which is capable of alcoholic fermentation, and *Kluyveromyces marxianus*, are unable to use pentoses and galacturonic acid (Edwards and Doran-Peterson, 2012). Therefore, there is currently a search for yeast strains capable of fermenting xylose and arabinose of rhamnogalacturonan I, which represents 18%–21% of dry weight in sugar beet pulp. For saccharification and fermentation, the sequential use of *S. cerevisiae* and bacteria such as *Escherichia coli* or *Erwinia chrysanthemi* has been proposed (Edwards and Doran-Peterson, 2012).

Recently it has been shown that enzymatic treatment of *Agave americana* biomass with *A. niger* pectinases remarkably improves saccharification compared to commercial enzymatic mixtures of cellulases and xylanases, without the need of prior treatment and with total conversion of polysaccharides to simple sugars (Wang *et al.*, 2019).

Introduction

Starch is a glucose polymer that is synthesized via photosynthesis in the chloroplasts of plants. It accounts for a large fraction of the biomass and serves as a reserve energy compound stored in plant organs such as tubers, seeds and roots (Norouzian *et al.*, 2005). Starch is metabolized through photorespiration, which requires amylases to break down the starch to glucose moieties. Amylases are glycoside hydrolases (EC 3.2.1) that hydrolyze the O-glycosyl compounds in starch and are found in animals, plants and microbes, with the preferred industrial source being microorganisms (Sun *et al.*, 2010).

Amylases are one of the oldest enzymes to be used commercially, dating back to 1984 when the α -amylase from *Aspergillus oryzae* known as “Taka diastase” was used in the pharmaceutical industry for digestive disorders (Gupta *et al.*, 2003). Since then, α -amylases have been extensively applied in several industries, including the bread and baking industry for improved volume, color and texture (Hamer, 1995).

Over the last few decades, starch-hydrolyzing enzymes have replaced the use of acid hydrolysis and are desirable for many different industrial uses due to their high degree of substrate specificity. Compared to chemical modification, the treatment of starch using enzymatic hydrolysis has several advantages, including better process control, higher product yields, faster reaction times at lower temperatures and cleaner effluents (Miao *et al.*, 2018). However, only a small number of bacterial and fungal strains meet the criteria for commercial amylase production, e.g., strains of *Bacillus* spp., *Aspergillus* spp. and *Rhizopus* spp. (Cereia *et al.*, 2006; Zeng *et al.*, 2011).

This chapter describes the different types of amylases, their properties, industrial applications and production processes, as well as predictions for the future amylase market.

Starch, the Natural Substrate for Amylases

Starch typically consists of a mixture of amylose and amylopectin molecules and the relative ratio of these polymers determines the diverse chemical properties of starch granules (van der Maarel *et al.*, 2002). Amylose (representing 10%–30% of the granule mass) is a linear polymer consisting of up to 6 000 glucose units linked by α -1,4 glycosidic bonds (de Souza and de Oliveira Magalhães, 2010). Amylose adopts a single helical structure that is randomly positioned within the amorphous lamella and is linked to the functional properties of starch. In contrast, amylopectin is a branched polymer that consists of short linear chains of 10–60 glucose units joined by α -1,4 bonds and α -1,6 linked side chains of 15–45 glucose units (Streb and Zeeman, 2012).

Starch in its native state is referred to as raw or unmodified (granular) starch. Raw starch granules have a densely compacted polycrystalline structure that resists enzymatic hydrolysis (Lin *et al.*, 2011). The starch granules are comprised of alternating semi-crystalline and crystalline shells and a large part of the amylopectin that forms the semi-crystalline shells is in the double-helical form, rather than the crystalline form. Starch is hydrolyzed into simpler carbohydrates called dextrins, with the dextrose equivalent (DE) indicating the fraction of the glycosidic bonds that has been hydrolyzed. For example, maltodextrin (DE 10–20) is an oligosaccharide used as a filler and thickener in the food industry, corn syrups (DE 30–70) are used as sweeteners, and dextrose (DE 100) is available as commercial glucose prepared by the complete hydrolysis of starch (Fellows, 2016).

At low temperatures (<50°C), granular starch is in its solid phase and insoluble in aqueous media (Cinelli *et al.*, 2015). However, starch granules undergo irreversible gelatinization when heated above a specific temperature. The starch gelatinization temperature is determined by the distribution and chain length of the amylopectin (Jane *et al.*, 1999) and is characterized by the phase transition of starch granules from an ordered to a disordered state (Ubwaa *et al.*, 2012). The breakage of the hydrogen bonds results in an uptake of water and swelling of the molecules, which leads to the disruption of the starch crystalline structure. Leaching of the amylose from the starch molecule takes place, resulting in the formation of soluble starch that is easy to hydrolyze (Daniel *et al.*, 2000). The conditions for starch gelatinization are determined by the plant type, degree of amylopectin cross-linking, as well as the salt, sugar and lipid content. Most A-type starches, which generally occur in cereal starches (such as wheat and corn), and are formed in warm and dry conditions (Ai and Jane, 2015). In contrast, B-type starches (B-type crystallites) are found in tubers, bananas and high-amylose starches, they are formed in cold and wet conditions and exhibit a lower gelatinization temperature (T_0 of 58.2°C) than A-type starches (Liu, 2005).

The hydrolysis of raw starch is significantly slower than that of soluble starch and higher enzyme loadings are required for its hydrolysis. When the four most economical native starches were compared for their susceptibility to hydrolysis, they were ordered (in diminishing order) corn $\geq$ wheat > cassava > potato (Szymanowska-Połańska *et al.*, 2012). Inefficient catalysis may result from various factors, including the physical architecture (degree of branching), the molecular structure of the solid substrate and the molecular configuration of the enzyme. Other factors that influence the hydrolysis of starch in its heterogeneous phase include enzyme diffusion in the medium, substrate accessibility, substrate recognition leading to adsorption, formation of the enzyme-substrate complex and catalytic action (Gallant *et al.*, 1997; Tawil *et al.*, 2011).

Role of Amylases in Starch Hydrolysis

Fungal starch hydrolyzing enzymes are found predominantly in the glycoside hydrolase (GH) family 13, with several examples occurring in the GH14 and GH15 families. Isoamylases (EC 3.2.1.68) and α -amylases (EC 3.2.1.1) are endo-type enzymes in the GH13 family that display α -1,4-cleavage activity and are responsible for the liquefaction of starch. The degradation of pullulan by pullulanases (EC 3.2.1.41, GH13) produces maltotriose (Gomes *et al.*, 2003), whereas isoamylases and pullulanases cleave α -1,6-bonds, thus converting amylopectin to amylose and oligosaccharides with 25–30 glucose residues. Exo-amylases (such as β -amylases, EC 3.2.1.2; GH14) only cleave α -1,4-glycosidic bonds, whereas glucoamylases (EC 3.2.1.3; GH15) and α -glucosidase (E.C. 3.2.1.20; GH13/GH31) display both α -1,4-cleavage and α -1,6-debranching activities (Sun *et al.*, 2010; Okuyama *et al.*, 2017). Compared to α -glucosidases that act better on short maltooligosaccharides, glucoamylases have a preference for hydrolyzing long-chain polysaccharides. The β -amylases hydrolyze the oligosaccharides from the non-reducing ends with the release of maltose residues (Tiwari *et al.*, 2015).

The GH13 family features 22 different substrate specificities involving α -glucosidic linkages, which include hydrolases, transglucosidases and isomerases (Møller *et al.*, 2016). The glycogen-debranching enzyme (GDE) plays a key role in carbohydrate metabolism and is highly conserved in animals and fungi (Nakayama *et al.*, 2001; Zhai *et al.*, 2016). The GH13_25 GDEs are bifunctional enzymes that exhibit both α -1,4-glucanotransferase (EC 2.4.1.25) and α -1,6-glucosidase (EC 3.2.1.33) activities. Zhai *et al.* (2016) expressed the *Candida glabrata* GDE (CgGDE) in *Escherichia coli* and the crystal structure showed four domains with an elongated structure, with the transferase and glucosidase domains being separated by two (middle) domains. The structures of the transferase and glucosidase active sites indicated that they are highly selective towards substrate branch length. The GDE transferase activity was similar to reactions catalyzed by members of the GH13 family, while the C-terminal end of the CgGDE displays an $(\alpha/\alpha)_6$ -barrel structure, similar to members of the GH15 family. However, the glucosidase part of GDEs was novel and has been classified into the new GH133 family (Møller *et al.*, 2016).

Complete starch degradation requires the hydrolysis of both α -1,4- and α -1,6-glycosidic bonds. Four groups of starch-converting enzymes confer this activity and include endo-amylases, exo-amylases, debranching enzymes and transferases, with enzymes from the first two groups being used for commercial starch hydrolysis. A schematic representation of the chemical structure of amylopectin and amylose and the respective sites for hydrolysis by the different types of amylases is shown in Fig. 1.

Depending on the starch composition and origin, α -amylases and glucoamylases would be sufficient for the complete degradation of amylose to D-glucose. The α -amylases would generate oligosaccharides, whose ends are degraded by glucoamylases to release D-glucose. This implies that organisms producing these two enzymes would be able to hydrolyze amylose into

Fig. 1 Chemical structure of amylopectin and amylose chains and the sites for hydrolysis by the different types of amylases.

D-glucose, but not necessarily utilize all the starch components (Peterson, 1998). Given the importance of these two enzymes, they will be discussed in more detail in the following sections.

Scanning electron microscopy (SEM) can be used to observe the hydrolysis of starch granules (Myburgh *et al.*, 2019). The two types of hydrolysis associated with native starch granules and α -amylase are 'centrifugal' (associated with regions and layers) and 'centripetal' (surface to center). Both these occur in corn, rice and wheat starch granules, whereas only centrifugal hydrolysis has been observed in potato starch granules (Sarikaya *et al.*, 2000). When α -amylases hydrolyze the interior linkages on the surface of starch granules, they provide the substrate for glucoamylases that hydrolyze the shorter dextrans from the non-reducing ends of the starch molecule to glucose. This centripetal type of hydrolysis results in the formation of small holes (pits), which allow the α -amylases to enter the interior of the starch molecule where they preferentially hydrolyze amorphous regions prior to crystalline areas. Pit formation is often referred to as "Swiss cheese hydrolysis" and is a characteristic manner in which cereal starch is degraded (Sujka and Jamroz, 2007). The synergistic action of the α -amylase-glucoamylase combination results in the complete degradation of raw starch into glucose units (Sun *et al.*, 2010). Wong *et al.* (2007) suggested that the ratio of α -amylase and glucoamylase activities can vary from 3:1 to 1:3, but efficient hydrolysis would only be possible if the α -amylase is in excess and there are sufficient activity levels for both enzymes (Görgens *et al.*, 2015).

α -Amylases

The GH13 family contains 42 subfamilies with fungal α -amylases (EC 3.2.1.1) grouped in subfamily GH13_1 (Chai *et al.*, 2016). This group comprises the largest family of glycoside hydrolases, with the majority of enzymes acting on starch, glycogen and related polysaccharides. An α -amylase consists of a single polypeptide chain that is folded into three domains (A, B, and C). Domain A is the catalytic domain, domain B has an irregular structure and domain C is believed to stabilize the catalytic site of the enzyme by protecting the hydrophobic patch (Singh and Kayastha, 2014). Most of the enzymes have an active site cleft between domains A and B where a triad of residues (Asp, Glu, and Asp) perform the catalysis. The α -amylases hydrolyze the internal α -1,4-bonds of amylose and amylopectin at random, producing maltodextrins with a length of 10–20 glucose residues, as well as maltose and free glucose (van Zyl *et al.*, 2012).

α -Amylases play a dominant role in carbohydrate metabolism and have entirely replaced the use of chemical hydrolysis in the starch-processing industry (Gupta *et al.*, 2003; de Souza and de Oliveira Magalhães, 2010). α -Amylases were the first enzymes produced for use on a commercial scale and the global α -amylase market is expected to reach USD 1.6 billion by 2020, growing at a compounded annual growth rate of 12.5% from 2016 to 2020, with the baking industry predicted to be the fastest-growing market at 15.0% per annum (Amylase market see "Relevant Websites section").

The molecular mass of α -amylases varies from 10 to 210 kDa, but microbial α -amylases are usually 50–60 kDa (Gupta *et al.*, 2003). Most α -amylases display maximum activity in the pH range of 4.5–7.0 (van Zyl *et al.*, 2012); thermostable acidic α -amylases are preferred for the industrial hydrolysis of starch since starch slurry has a pH around 4.5 (Sharma and Satyanarayana, 2013). In contrast, alkaline amylases are desirable for the detergent and food industries (Das *et al.*, 2004), thus prompting searches for microbial strains producing these α -amylases. From an economic and technical perspective, thermostable α -amylases are beneficial as they allow for higher operational temperatures. However, recombinant α -amylases with optimum activities at 30–37°C will increase the rate of starch hydrolysis at the growth temperature of the yeast host strains (Carrasco *et al.*, 2016).

Amylases fulfill a wide range of applications and have been investigated for over 30 years to identify the important determinants for enzyme function (Ju *et al.*, 2019). Both the DNA and amino acid sequences of several α -amylases have been included in comparative studies (Imanaka and Kuriki, 1999; Janaček *et al.*, 1997). It revealed large variation in the length of the open reading frames (Kajiwara *et al.*, 1997) and assisted functionality studies of its different domains (MacGregor *et al.*, 2001), e.g., unraveling the evolutionary origin of the α/β -barrel of α -amylase (Farber and Petsko, 1990; Farber, 1993). A selection of these enzymes and some of their key properties are summarized in Table 1.

Glucoamylases

Glucoamylases (glucan α -1,4-glucosidase, EC 3.2.1.3) are grouped in GH15 family and are exo-acting enzymes that catalyze the hydrolysis of α -1,4- and α -1,6-glucosidic linkages to release the inverted β -D-glucose from the non-reducing ends of starch (Chen *et al.*, 2012). As indicated in Table 1, glucoamylases are produced by a wide range of microorganisms, but enzymes for commercial applications are mainly produced by filamentous fungi as they secrete large quantities of the enzyme. The industrial production of glucoamylases has focussed on *Aspergillus niger*, *Aspergillus awamori* and *Rhizopus oryzae* due to the stability of their enzymes (Lin *et al.*, 2007).

These enzymes are mainly used for the production of glucose syrup, high-fructose corn syrup and bioethanol, and have the ability to degrade large oligosaccharides containing up to 90% α -1,6-linkages. The pH and temperature optima of glucoamylases are generally in the range of 4.5–5.0 and 46–60°C, respectively, and they are relatively stable at higher temperatures (van Zyl *et al.*, 2012). A few thermophilic strains produce a glucoamylase with an optimum temperature of 70°C, such as *Talaromyces emersonii* (now *Rasamsonia emersonii*), *Halvina lanuginosa* and *A. niger* IMDC No. 120 (James and Lee, 1997). The molecular mass of glucoamylases can vary from 55 kDa (raw starch-degrading glucoamylase from *Saccharomycopsis fibuligera*) to about 300 kDa (glucoamylase from *Saccharomyces cerevisiae* var. *diastaticus*) (Hostinová and Gašperík, 2010).

Table 1 Properties of a selection of fungal and yeast amylases

	Amylase	pH optimum	Temperature optimum (°C)	Starch digestion	Reference
Filamentous fungi

Note: α – α -Amylase, G – Glucoamylase.

Starch Binding Domain (SBD)

Carbohydrate-binding modules (CBMs) are non-catalytic ancillary domains that function independently of the catalytic domain and are often present in glycoside hydrolases. CBMs that have an affinity for insoluble raw starch are generally referred to as SBDs (Peng *et al.*, 2014). The SBD is usually composed of about 100 amino acid residues and is present in a number of amylolytic enzymes. It is comprised of several β -strand segments forming an open-sided, distorted β -barrel structure and it is connected to the catalytic domain by a glycosylated linker region (Juge *et al.*, 2002; Barchiesi *et al.*, 2015).

The SBD plays a fundamental role in granular starch hydrolysis by performing several simultaneous functions. It binds to the starch molecules and thereby increases the concentration of the substrate at the catalytic site. A strong correlation between raw starch hydrolysis and the adsorption of amylases to raw starch granules has been described for bacterial, yeast and fungal α -amylases and glucoamylases (Mitsuiki *et al.*, 2005). The SBD may also disturb the structure of the starch by disrupting polysaccharide chain interactions on the granule's surface, which enhances the amylolytic rate (Santiago *et al.*, 2005; Barchiesi *et al.*, 2015).

Sequence-based classification divides SBDs into ten CBM families, namely 20, 21, 25, 26, 34, 41, 45, 48, 53, and 58 (Peng *et al.*, 2014). The diverse CBM20 family has been shown to function in raw starch binding with two starch-binding sites (SBS) that are positioned on the exterior of the active site area (Cockburn *et al.*, 2014), presumably with different functions. It has been reported that site 1 is probably used as the initial starch recognition site, whereas site 2 is associated with the subsequent binding to the starch polymer (Sorimachi *et al.*, 1997). The CBM20s are grouped based on their amino acid sequences, substrate binding specificities and position in the protein (middle, N- or C-terminal) (Barchiesi *et al.*, 2015). CBM20s are predominantly associated with starch-active proteins from GH families 13, 14, 15 and 77, but GH families 14, 31, 57, 97, and 119 also contain the CBM20 (Møller *et al.*, 2016). Microbial amylases that are involved in raw starch metabolism often contain an SBD at the C-terminus of the protein (Latorre-García *et al.*, 2005), except for the α -amylase from *Thermoactinomyces vulgaricus* and the glucoamylase from *R. oryzae* that contain an N-terminal SBD (Santiago *et al.*, 2005).

Application of Amylases

As indicated in Fig. 2, amylases play a key role in industry with applications ranging from the production of high-fructose syrups, corn bioethanol, detergents, textile and paper industries, food industries (baking and chocolate industry) to newer biopharmaceutical applications (Gupta *et al.*, 2003; Saini *et al.*, 2017). It is thus not surprising that amylases represent 25%–30% of the global enzyme market and have the largest market share of all enzyme groups (de Souza and de Oliveira Magalhães, 2010; Saranraj and Stella, 2013). The value of the starch enzyme and starch bioethanol markets alone was estimated to be worth \$2.24 billion in 2018 (Mehta and Satyanarayana, 2016). A selection of these applications are discussed in more detail in the following sections.

Fig. 2 Amylases are used in a variety of industrial applications, ranging from food to transport fuel.

Production of High-Fructose Corn Syrups

The production of high-fructose corn syrups (HFCS) represents the largest application of starch in the beverage (beer) and soft-drinks markets. The production of HFCS comprises of three steps: liquefaction, saccharification and isomerization. During liquefaction, starch is heated in a jet cooker to 105–110°C for a short period and then partially hydrolyzed at 95°C using a thermostable α -amylase that produces shorter oligosaccharides by an endo-wise random disruption of the large molecules (Fujii *et al.*, 1988). After cooling to 55–60°C and pH adjustment to 4–5, saccharification of the liquefied starch is performed with a fungal glucoamylase to generate glucose-rich dextrins. In a third step, about half of the glucose is converted to fructose with the aid of glucose (xylose) isomerase. The bulk of HFCS is used in the production of soft-drinks (Mehta and Satyanarayana, 2016), but glucose-rich syrups are also used as a supplement in high-gravity beer brewing to ensure high ethanol concentrations (Casey *et al.*, 1984).

Biofuel Production From Starch

After high-sugar syrups, first-generation ethanol production from hydrolyzed starch is the second-largest industrial application of amylases. The first two steps are equivalent to the production of high-sugar syrups, namely liquefaction with thermostable α -amylases, followed by saccharification with glucoamylases. First, the starch slurry is gelatinized in a jet cooker at 100–105°C for 5 min, followed by a liquefaction step using thermostable α -amylase at high temperatures (>95°C for up to 3 h). The saccharification step involves cooling of the slurry to 60°C and the addition of a glucoamylase to release the fermentable sugars (Białas *et al.*, 2014; Mehta and Satyanarayana, 2016; Robertson *et al.*, 2006). The sugars are subsequently fermented to bioethanol, which is distilled and used as a gasoline extender.

The conventional process of cooking the starch during liquefaction has several disadvantages, such as the high energy input (up to 30%–40% of the ethanol value) required for gelatinization, and pH adjustment steps (Lim *et al.*, 2003). Commercial α -amylases function optimally at pH 6–6.5 and the pH of the fermentation broth needs to be lowered to pH 4–5 before glucoamylase addition and fermentation (Robertson *et al.*, 2006). The use of granular/raw starch-hydrolyzing enzymes can eliminate the high temperatures required for starch gelatinization and improve the efficiency of starch-to-ethanol conversion using simultaneous saccharification and fermentation (SSF) (Gohel and Duan, 2012). There are several commercial granular starch hydrolyzing enzyme (GSHE) cocktails available that can be used in combination with a fermenting yeast. These amylases can hydrolyze the raw starch at relatively low temperatures; 48°C is recommended for SSF, after which the fermentation broth is cooled to 30°C prior to yeast addition (Görgens *et al.*, 2015).

Food and Beverage Markets

Mass production of bread in the baking industry faces several challenges, such as proper leavening to provide volume, improved texture and taste, as well as improved shelf-life. Amylases have been used since the mid-1900s to address these challenges. The addition of α -amylase allows for the hydrolysis of smaller starch particles during bread leavening, thus reducing the viscosity of the dough. This allows for proper bubble formation during the release of CO₂ by the bakers' yeast and releases additional sugars for the yeast, thus prolonging the fermentation phase. The volume of the bread increases, the texture improves and the prolonged fermentation can also contribute to the taste. The addition of amylases also limits drying of the bread and firming of the crumb during storing – a process called staling. However, it is important not to overdose with α -amylase, which can result in a sticky dough that counters the positive effects. More recently, further emphasis has been placed on the use of debranching amylases, such

as pullulanases, that generate dextrans with a degree of polymerization (DP) of 4–9, which is ideal for anti-staling and avoiding stickiness (Goesaert *et al.*, 2009; Gupta *et al.*, 2003; Tiwari *et al.*, 2015).

Several beverage industries rely on amylases. Chocolate slurries are rich in starch, which negatively affects the application of chocolate syrups. Amylases are added to remove excessive dextrans and thus lower the viscosity to improve the flow properties of chocolate syrups in confectionery mixtures (Tiwari *et al.*, 2015). Apple juice contains up to 15% starch, which can slow down filtration due to membrane fouling and cause high viscosity and hazing of the juice. The addition of amylases can address these problems and assist in clarifying the juice (Carrín *et al.*, 2004). Barley α -amylase is used in the brewing industry to maximize the release of fermentable sugars and the Milliard reaction to ensure the characteristic color of wort during beer making. Although the addition of exogenous amylases can be advantageous, it is not allowed in the beer industry. Germination of barley during malting is therefore precisely controlled to provide sufficient endogenous amylases for the production of wort (Bamforth, 2009). Fungal amylases are also extensively used in the preparation of oriental foods like tempeh, soy sauce, koji stage, idli and many other fungal foods (Saini *et al.*, 2017).

Amylase in Animal Feeds

Amylases have found application in the feeds of monogastric animals, such as chickens and pigs. The starch component in the typical corn-soy diet of broiler chickens is the primary source of energy to promote fast growth. However, the inevitable presence of non-starch polysaccharides (e.g., arabinoxylan) in the diet can impede starch utilization. Moreover, the high feed rate of modern broilers can cause limited starch digestion despite the production of endogenous amylases by hatchlings. The addition of exogenous amylases to assist in starch digestibility has been shown to positively impact energy release and growth in broiler chickens. By supplementing with additional enzymes, such as xylanases to hydrolase the arabinoxylan, it reduces the viscosity of the feed in the stomach and enhances feed conversion (Stefanello *et al.*, 2017, 2015).

For piglets, the most stressful phase is directly after abrupted weaning from the sow. Their digestive tracts have to adapt from frequent milk feeding to ad-libitum feeding (free feeding) on solid foods, mostly plant-based feeds in dry format. Under- or overfeeding could affect the integrity of the gut microflora or proliferation of pathogenic bacteria. The addition of exogenous hydrolases helps with the adaptation to the more complex plant-based feeds. However, since piglets produce their own endogenous amylases, the effect of amylase addition to the feed of weaning piglets has a marginal effect and is not as dramatic as, for example, the addition of phytase enzymes (Torres-Pitarch *et al.*, 2017).

Detergent Industries

Traditional chemical detergents used for cloth- and dishwashing are too harsh for delicate clothes, as well as dangerous when accidentally ingested. The introduction of enzymes, such as proteases, amylases and mannanases allows for environmentally-friendly detergents for automatic washing in much milder conditions, including cold water for clothing. More than 90% of modern detergents contain amylases for the removal of starchy stains from potatoes, gravies, chocolate and custards (de Souza and de Oliveira Magalhães, 2010; Gupta *et al.*, 2003). However, amylases for the detergent industry should be thermostable and able to function at an alkaline pH (Singh *et al.*, 2016).

Textile and Paper-and-Pulp Industries

Starches are used in the textile and paper-and-pulp industries to enhance the production and the quality of end-products. Weaving exerts mechanical stress on fabric yarns, which are usually covered with a starch coat to facilitate weaving. However, this starch coat has to be removed from the fabrics (a process called desizing) before the fabric can be bleached and colored. Amylases are used to selectively remove the starch by converting them to soluble dextrans without attacking the yarn fibers (de Souza and de Oliveira Magalhães, 2010; Gupta *et al.*, 2003). Similarly, starch is incorporated during papermaking to enhance the stiffness and strength of paper, whilst providing a superior finishing that enhances the writing and erasability properties. The starch has to be of a constant high DP and low viscosity to ensure uniform coating. Amylases are therefore used to modify the raw starch to the correct consistency required for coating (de Souza and de Oliveira Magalhães, 2010; Gupta *et al.*, 2003; Tiwari *et al.*, 2015).

Clinical and Medicinal Applications

Since Stocks (1916) suggested that amylase activity in the blood and urine of patients could indicate pancreatic enzyme production, the amylase test has been used as a diagnostic test for pancreatic disorders. In recent years, newer applications for amylases in pharmaceuticals have been established. A slow release of compounds is required for effective drug delivery; an example is the use of cross-linked amylose (CLA) compressed with drug powder for slow-release, which can be controlled by the ratio of CLA to drug powder. The compressed drugs are stable in the dry formulation and require rehydration of the CLA after ingestion before amylases can degrade the CLA/drug matrix (Dumoulin *et al.*, 1999).

Production of Industrial Amylases

Enzyme are industrial catalysts and they need to tolerate the relatively harsh conditions that are often associated with industrial processes. The pH profile, pH stability and thermostability of enzymes are important factors to be considered in the development of enzyme production processes (de Souza and de Oliveira Magalhães, 2010). Industrially important enzymes have traditionally been produced using submerged fermentation, where different parameters (e.g., pH, temperature, aeration, oxygen transfer, and moisture) can be controlled. Solid-state fermentation systems offer a promising alternative, since they resemble the natural habitat of several microorganisms (de Souza and de Oliveira Magalhães, 2010; Sundarram *et al.*, 2014). Bulk enzyme production requires minimal downstream processing and is often used as crude preparations, whereas enzyme applications in pharmaceutical and clinical sectors require high purity amylases (de Souza and de Oliveira Magalhães, 2010).

The suitability of enzymes for large-scale production is influenced by the yield, stability and production costs (Naidu and Saranraj, 2013; Das *et al.*, 2011). Emerging genetic engineering tools have facilitated the use of recombinant amylases that further promoted their use in industrial applications (Muralikrishna and Nirmala, 2005), in particular with the aim of obtaining enzymes with desired or enhanced characteristics (Abdel-Fattah *et al.*, 2013). Furthermore, low-value agricultural residues have gained much interest as an inexpensive substrate for recombinant enzyme production (Kim and Dale, 2004).

Recombinant Production of Amylases

Various amylases have been cloned and expressed in bacterial and yeast strains for a number of reasons, including understanding enzyme characteristics, increasing enzyme titers and developing enzymes with novel properties (Sivaramakrishnan *et al.*, 2006; Miao *et al.*, 2018).

Recombinant strains have also been constructed to express highly active amylases for use in industrial biofuel production (Cripwell *et al.*, 2019a). The main challenge in engineering a robust amylolytic yeast is the ability to hydrolyze raw starch at high concentrations, while simultaneously fermenting the hydrolyzed sugars to ethanol (Favaro *et al.*, 2015). Compared to laboratory strains, industrial strains have valuable characteristics, including enhanced tolerance to ethanol, acids and sugars. A well-used transformation platform for the heterologous expression of foreign genes in *S. cerevisiae* uses high-copy 2-micron plasmids that can be maintained at around 10–50 copies per cell. However, industrial *S. cerevisiae* strains cannot be genetically engineered using these plasmids as plasmid stability requires the use of selectable markers and thus the need to maintain selection pressure (Shi *et al.*, 2016). Stable chromosomal integration is thus required to engineer robust industrial *S. cerevisiae* yeast strains to produce extracellular amylases (Favaro *et al.*, 2013).

An in-depth understanding of heterologous gene expression in *S. cerevisiae* has been generated over the last few decades with a wide range of genetic tools available for strain development and improvement. In addition, the genetic competence of *S. cerevisiae* strains to accept foreign DNA has facilitated targeted chromosomal manipulations. However, the lack of native starch-hydrolyzing enzymes in *Saccharomyces* species has limited its application in the starch bioprocessing industry (Eksteen *et al.*, 2003a), with the exception of the amylolytic *Saccharomyces diastaticus* strain (Adam *et al.*, 2004).

Amylolytic Strains for Biofuel Production

Constructing a starch-degrading yeast requires the genetic engineering of industrial yeast strains that can produce high levels of heterologous amylolytic activity. This strain would theoretically lead to higher ethanol production from starch without requiring pre-treatment of the substrate (Mukerjee *et al.*, 2006). It would be beneficial if the different amylases originate from the same organism, thus complementing one another thanks to evolutionary development and compatibility. Screening for novel amylolytic enzymes is thus essential to generate a sufficiently large collection of raw starch-degrading glucoamylases and α -amylases that can be heterologously produced by fermenting yeast strains. Ideally, these recombinant enzymes should have the characteristic raw starch-binding sites within the SBD. Different strategies have been employed to produce amylases in *S. cerevisiae*, with cell-surface display and consolidated bioprocessing among the favorites.

The use of a cell-surface display technique has allowed for the expression of amylase genes on the surface of a cell through linkage with a genetically fused anchor protein that keeps the amylase cell-bound. To construct yeast strains with the ability to hydrolyze starch as a substrate for bioethanol production, the cell-surface display technique can be combined with metabolic engineering approaches to manipulate target pathways within yeast cells. This would ensure that bottlenecks in sugar utilization do not negatively affect ethanol productivity and could result in the construction of novel microbial factories for the production of value-added compounds (Tanaka and Kondo, 2015). Several groups have produced ethanol from starchy biomass using this engineering approach, for example, Shigechi *et al.* (2004) co-displayed the *R. oryzae* glucoamylase and bacterial *Streptococcus bovis* α -amylase to produce ethanol directly from raw corn starch.

Consolidated bioprocessing (CBP) combines enzyme production, substrate hydrolysis and glucose fermentation into a one-step process using a single organism, and is used for bioethanol production at low temperatures (van Zyl *et al.*, 2012). Amylolytic strains for efficient CBP of natural starchy biomass were first described by Favaro *et al.* (2015) when codon-optimized variants of the *Thermomyces lanuginosus* glucoamylase (TLG1) and *Saccharomycopsis fibuligera* α -amylase (SFA1) genes were δ -integrated into two *S. cerevisiae* strains with promising industrial traits. However, the challenge remains to construct strains that can produce ethanol concentrations

comparable to the >20% v/v ethanol reached in the conventional starch-to-ethanol process (Görgens *et al.*, 2015; Walker and Walker, 2018). Currently, there is no industrial process that uses a recombinant amylolytic yeast strain (producing both an α -amylase and glucoamylase) for starch CBP. Although commercially available glucoamylase-producing *S. cerevisiae* strains are available, they lack the α -amylase required for the liquefaction of starch. There is thus a strong demand for a drop-in CBP yeast that simultaneously expresses raw starch α -amylase and glucoamylase-encoding genes for complete starch (raw) hydrolysis.

Several studies have screened raw-starch fungal amylase-glucoamylase gene combinations in laboratory *S. cerevisiae* strains. The *amyA* α -amylase and *glaA* glucoamylase genes from *Aspergillus tubingensis* (Viktor *et al.*, 2013), as well as amylases originating from *Aspergillus terreus* (Sakwa *et al.*, 2018), *Aureobasidium pullulans*, *Neosartorya fischeri*, *Rhizomucor pusillus*, *T. emersonii*, *Talaromyces stipitatus*, and *Thermomyces lanuginosus* (Cripwell *et al.*, 2019a) have been cloned and expressed in *S. cerevisiae* Y294 laboratory strains, with varying abilities to degrade raw starch under fermentation conditions.

Recently, Cripwell *et al.* (2019b) integrated α -amylase and glucoamylase genes originating from *T. emersonii*, into the Ethanol Red™ industrial *S. cerevisiae* strain and demonstrated efficient conversion of raw corn starch to ethanol under high substrate loadings. Myburgh *et al.* (2019) further demonstrated that this amylolytic strain could be used for the fermentation of broken rice. These breakthroughs represent significant progress towards constructing CBP strains that produce fungal amylases for the biofuel industry and demonstrate the use of different raw starch substrates as feedstock.

Searching for Novel Amylases

Although a number of amylases have been identified from various microbial sources (Sun *et al.*, 2010), there is still a large number of unknown or poorly characterized microorganisms in nature and uncharacterized proteins from sequencing projects that could be explored for improved amylase production (Helbert *et al.*, 2019). In addition, several approaches can be pursued to improve the properties of (known) enzymes that would render them more effective as biocatalysts. These include protein engineering using saturated mutagenesis, error-prone PCR and gene shuffling coupled to high-throughput screening (Miao *et al.*, 2018). Metagenomic approaches and metatranscriptomic analyses can assist with the search for amylases with higher enzyme yields, activity and stability. Furthermore, recent advances in bioinformatics have made it possible to identify new enzymes through database mining of available sequencing data (Li *et al.*, 2012). For example, Pel *et al.* (2007) described the genomic DNA sequence of *A. niger* strain CBS 513.88, a filamentous fungus widely used in industry to produce enzymes and organic acids. Yuan *et al.* (2008) combined the sequencing data from the genome of *A. niger* CBS 513.88 with microarray experiments to identify novel enzymes. They reported 17 previously unknown enzymes from the GH13, 15 and 31 families with at least eight genes that encode α -amylases. When these genes were expressed in *Pichia pastoris*, the recombinant AmyG and AmyE α -amylases exhibited acid-stability and high levels of maltotriose being produced, making them potential candidates for applications in both the food and starch processing industries (Wang *et al.*, 2018).

Metatranscriptomic analysis is another approach that provides a direct and efficient sequence-based method to mine for novel enzymes. Yi *et al.* (2018) successfully obtained a thermostable α -amylase from Chinese Nong-flavor liquor. The enzyme displayed high stability at 60°C, acidic pH optima at 5.0–5.5 and was more efficient towards amylopectin hydrolysis, compared to amylose hydrolysis. Thermostable enzymes are attractive catalysts for many biotechnological processes and play a crucial role in the conventional starch to ethanol process.

Future Outlook

The global market for industrial enzymes was estimated to be around \$4.2 billion in 2014 (Singh *et al.*, 2016) and due to a large demand for industrial amylases by various industries (specifically dairy and baking), it has been predicted that the global α -amylase baking enzyme market will reach \$382.4 million by 2025 (Global amylase market see “Relevant Websites section”). There are several factors that are driving the growth of the amylase market, with food quality and environment-friendly manufacturing process being high on the list (Food enzyme market see “Relevant Websites section”).

Biotechnological advances have positively benefited the production of new and improved amylases, thus increasing the global demand for these enzymes. The search for novel amylases is a continuous process (Mobini-Dehkordi and Javan, 2012) with a growing demand for industrial amylases for applications in beverage production (milkshakes, juices, wine and beer), pharmaceuticals and detergents (Global amylase market see “Relevant Websites section”). Furthermore, advances made with modified enzymes are expected to propel the use of amylases on a global scale since amylase properties can be tailored for improved performance under industrial conditions.

Applications of Fungal Inulinases

Ritumbhara Choukade and Naveen Kango, Department of Microbiology, Dr. Harisingh Gour Vishwavidyalaya (A Central University), Sagar, Madhya Pradesh, India

© 2021 Elsevier Inc. All rights reserved.

Introduction

Inulin: General Introduction, Distribution, Annual Production and Availability

The global inulin market is expected to exceed USD 2.5 billion by 2023. In 2015, the global market size for inulin production and consumption was estimated at over 250 kg tonnes and is likely to exceed 480 kg tonnes by 2023 with an increase of 8.5% (See Relevant Websites section). The European inulin market size was projected over 125 kg tons in 2015 and is expected to gain a moderate increase in upcoming years. The highest gain in inulin market that of more than 10% during 2016–2023, was estimated in Asia Pacific due to a boost in consumption of functional foods and dietary fibers particularly in India, Australia, and China.

Inulin, a fructan, is a storage polysaccharide mainly composed of a fructofuranose backbone connected by β (2 $\rightarrow$ 1) glycosidic linkages with a terminal glucose entity (Kango and Jain, 2011). A (1 $\leftrightarrow$ 2)-bonded α -D-glucosyl group forms the terminal end of the inulin backbone (Fig. 1). It is the second most abundant plant storage carbohydrate polymer after starch and categorized as non-digestible carbohydrate as its fiber does not get digested in the colon. The fructose chain length varies from 2 to 60 monomeric units in an inulin molecule. When inulin is composed of a maximum of 10 fructose units, it is referred to as inulooligosaccharide (IOS) or fructooligosaccharide (FOS) or oligofructose. Inulin is found in several tropical and temperate plants as a major storage polysaccharide (Table 1). Apart from the prominently known inulin sources such as chicory, Jerusalem artichoke and dahlia, several common fruits, vegetables and cereals like onion, garlic, leek, tomato, banana, wheat, rye and barley are also some sources of inulin (Mensink et al., 2015).

Inulinases: Characteristics, Production and Heterologous Expression

(1) Types of inulinases

Based on the type of the end products generated by their action, inulinases are classified into fructose generating exo-inulinases and oligosaccharide generating endo-inulinases.

- (a) *Exo-inulinase* (EC 3.2.1.80; β -D-fructanfructohydrolase or EC 3.2.1.153; β -(2,1)-D-fructanfructohydrolase): Exo-inulinase (EC 3.2.1.80) catalyzes the hydrolysis of terminal and non-reducing (2 $\rightarrow$ 1)-linked β -D-fructofuranose residues in fructans, while the other exo-inulinase (EC 3.2.1.153) hydrolyzes the terminal, non-reducing (2 $\rightarrow$ 1) and (2 $\rightarrow$ 6)-linked β -D-fructofuranose residues in fructans and generates fructose (Fig. 2). Another relevant enzyme, sucrase (EC 3.2.1.26; β -D-fructofuranoside fructohydrolase or invertase) is also involved in the hydrolysis of terminal non-reducing β -D-fructofuranoside residues in β -D-fructofuranose and sucrose.
- (b) *Endo-inulinase* (EC 3.2.1.7; 1- β -D fructanfructanohydrolase): Endo-inulinases are also referred as 1- β -D fructanfructanohydrolases that catalyze hydrolysis of (2 $\rightarrow$ 1)- β -D-fructosidic linkages within the main chain of inulin or polyfructose (Fig. 2).

Inulinases (exo and endo) and related enzymes such as fructosyltransferase, levan hydrolase and β -fructofuranosidase are categorized in glycoside hydrolase (GH) family 32 in the Carbohydrate-Active EnZymes (CAZy) database (Lombard et al., 2014; Trollope et al., 2015).

(2) Structural characteristics of inulinases

In the Enzyme Commission classification, inulinases belong to the group glycosidases (EC 3.2.1) of the glycosylases sub-class (EC 3.2). Crystal structure data of a fungal endo-inulinase, INU2, from *Aspergillus ficuum* has a 3-D structure sharing five β -strands organized as two β -sheets in a C-terminal β -sandwich domain. The N-terminal domain of the structure is composed of a 5-fold β -propeller catalytic domain with four β -sheets. The structure revealed that it has an extra inulin binding pocket formed by a conserved amino acid motif, W-M(I)-N-D(E)-P-N-G, and two loops. This structure includes Trp40, which plays a critical role in the catalysis of third unit of inulin and inulin-like substrates (Pouyez et al., 2012). Inulinases and related enzymes have WMN(D/E)PN, RDP, SVEVF and EC (P) motifs (Fig. 3) as their conserved domains in the primary structure showing the involvement of conserved amino acid sequences in their catalytic mechanism (Park et al., 2003; Nagem et al., 2004; Kango and Jain, 2011). Exo-inulinases produced by the yeasts *Kluyveromyces marxianus* and *Pichia guilliermondii* are devoid of the SVEVF motif in their conserved domain (Liu et al., 2013). Inulinase from *K. marxianus* Y-303 had 27% α -helices, 28% β -sheets and 45% unordered structures in its secondary structure (Holyavka et al., 2016). The catalytic action of most of the glycoside hydrolases, including inulinase, involves two acid residues that act as nucleophile and proton donor. Site-specific mutagenesis and chemical modification procedures unraveled the catalytic functions of yeast inulinase carried out by

Fig. 1 Structure of inulin (Vandamme and Derycke, 1983). F-Fructose, G-Glucose.

Table 1 Some common sources of inulin

Source	Plant part	Inulin content (%)
Onion	Bulb	2–6
Jerusalem artichoke	Tuber	14–19
Dahlia	Tuber	9–12.5
Chicory	Root	15–20
Leek	Bulb	3–10
Garlic	Bulb	9–16
Artichoke	Leaves-heart	3–10
Banana	Fruit	0.3–0.7
Rye	Cereal	0.5–1
Barley	Cereal	0.5–1.5
Dandelion	Leaves	12–15
Burdock	Burdock	3.5–4.0
Camas	Bulb	12–22
Murnong	Root	8–13
Yacon	Root	3–19
Salsify	Root	4–11
Sweetleaf	Leaves	8–23
Suma	Roots	11.45

the Asp23 and Glu204 amino acids belonging to the conserved part of WMN(D/E)PN and EC(P) sequences (Reddy and Maley, 1990).

(3) Production and properties of inulinases

A number of fungal and yeast strains have been reported to secrete high titers of extracellular inulinases. Several *Penicillium* spp. sourced from Jerusalem artichoke fields were found to produce inulinases, among which *Penicillium subrubescens* FBCC 1632 was selected as an efficient inulinase producer (Mansouri et al., 2013). Recombinant inulinases sourced from *A. ficum*, *Aspergillus niger* and *Penicillium janthinellum* were expressed in the yeast, *Pichia pastoris* resulting in high yield of inulinases (Chen et al., 2013; He et al., 2014; Chen et al., 2015). Some other yeast such as *K. marxianus*, *Cryptococcus aureus*, *Meyerozyma guilliermondii* and *Zygosaccharomyces cerevisiae* are also reported to produce inulinases (Rawat et al., 2017a). *Penicillium oxalicum* produced 322.1 U/gds (per gram dry substrate) exo-inulinase when grown on carrot pomace (Singh et al., 2018), whereas *Aspergillus awamori* produced 2.2 U/mg exo-inulinase when grown on asparagus root extract medium (Rawat et al., 2015a). *Aspergillus fumigatus* and some *Penicillium* spp. were able to produce exo- and endo-inulinases during growth on dahlia or asparagus root and tuber extract medium (Rawat et al., 2015a).

Exo-inulinases are also produced by several fungi, yeast and bacteria, among which Aspergilli are recognized as a prominent source of exo-inulinases. Several reports ascertained the use of agro-waste or plant biomass for inulinase production by fungi (Das et al., 2019a). Utilization of inulin-rich plant biomass for inulinase production is a cost-effective and eco-friendly approach. *A. niger* is well known for the production of high titers of exo-inulinase in solid state fermentation (SSF). It has been reported to produce 11.13 U/gds of exo-inulinase on Jerusalem artichoke and bean, while 137.2 U/gds and 200 U/gds when grown on rice bran and banana peels, respectively (Narayanan et al., 2013; Al-Dabbagh and Mahmood, 2015). Other members of this genus, *Aspergillus parasiticus*, *Aspergillus terreus* and *Aspergillus versicolor* are reported to produce exo-inulinase on sugarcane bagasse, artichoke leaves, garlic wastes, chicory roots and orange rinds, respectively (Abd El Aty et al., 2014). *Penicillium brevicompactum* produced 1.24 U/gds and 0.66 U/gds exo-inulinase on artichoke leaves and garlic waste, respectively, while *Penicillium rugulosum* produced 239 U/gds exo-inulinase on copra waste substrate (Abd El Aty et al., 2014; Dilipkumar et al., 2014). Other than filamentous fungi, some yeasts such as *Cryptococcus*, *Geotrichum*, *Kluyveromyces* and *Saccharomyces* are well known sources of exo-inulinase. *C. aureus* produced 420 U/gds exo-inulinase on wheat bran and rice husk substrates (Sheng et al., 2009). Other studies suggested that *K. marxianus* is among the best yeast for exo-inulinase production on low-cost substrates. *Kluyveromyces* S120 was reported to produce 409.8 U/gds inulinase on wheat bran, while another *K. marxianus* strain produced 106.72 U/gds and 21.23 U/gds activities on coarse wheat bran and corn flour substrate, respectively (Selvakumar and Pandey, 1999; Xiong et al., 2007). Another isolate of *K. marxianus* produced 463 U/gds inulinase on sugarcane bagasse (SCB), cane molasses and soybean bran while it produced 586 U/gds inulinase on mixed SCB and soybean meal (Mazutti et al., 2010). Dimorphic yeast, *Geotrichum candidum*, resulted in a similar level of 412 U/gds inulinase when grown on leek powder (Canli and Kurbanoğlu, 2012).

(4) Inulinase assay and characterization

It is important to understand some important aspects of the inulinase assay with regard to the choice of substrate, as inulin from various sources (e.g., chicory and dahlia inulin) shows variability. The amount of enzyme that catalyzes formation of 1 μ mol of fructose in one minute from inulin (usually 0.5–1.0% w/w chicory inulin) is defined as one inulinase unit, while the invertase or fructofuranosidase unit is defined as the amount of enzyme that generates 1 μ mol of fructose or glucose from sucrose (Kango, 2008; Rawat et al., 2015a). Exo-inulinases catalyze the exo-hydrolysis of the

Fig. 3 Multiple alignment of some *Aspergillus* inulinases amino acid sequences. Sequences have been selected from GenBank and aligned using CLUSTAL W software for multiple alignment. Sources of fungal inulinases: *Aspergillus lacticoffeatus* CBS 101883 (PYH56754.1); *Aspergillus phoenicis* (RDK37757.1); *Aspergillus niger* (EHA25512.1); *Aspergillus fumigatus* (KEY80659.1); *Aspergillus awamori* exo-inulinase (CAC44220.1); *Aspergillus udagawae* (GA081637.1); *Aspergillus arachidicola* (PIC87873.1); *Aspergillus ficuum* (CAA07345.1); *Aspergillus homomorphus* (RAL14360.1); *Aspergillus welwitschiae* exo-inulinase (RDH30424.1).

inulin molecule and, therefore, also show invertase activity while, endo-inulinase lacks this activity. Usually, 0.5–1.0% inulin (Chicory) in citrate buffer (pH 5.0 at 50°C) is used for the inulinase assay (Rawat *et al.*, 2015a). This assay is based upon estimation of the fructose equivalents generated from the inulin polymer, but does not distinguish between exo- and endo-inulinases. These can be distinguished on the basis of end-product analysis of hydrolysis using thin layer chromatography (TLC) or high performance liquid chromatography (HPLC) (Rawat *et al.*, 2015a). The hydrolytic activity of exo-inulinase can be distinguished from invertase by the determination of I/S ratio that is the relative activity towards inulin and sucrose. Higher value of I/S ratio indicates greater affinity of the hydrolase towards inulin as compared to sucrose.

(5) Cloning and over-expression of inulinase

As for other commercial enzymes, cloning and heterologous expression of exo- and endo-inulinases in bacterial and yeast hosts for enhanced yield has been attempted by several workers. Yeasts play an important role as expression host as they have the ability to grow faster than filamentous fungi and can produce high amounts of eukaryotic or processed proteins. Exo-inulinase from *A. niger* was co-expressed with a gene from *Saccharomyces cerevisiae* named *hac1*, which increases protein folding and secretory pathways of eukaryotic proteins from the endoplasmic reticulum, in *P. pastoris*. The growth of the recombinant *P. pastoris* strain resulted in 95% inulin conversion into fructose (Chen *et al.*, 2016). Endo-inulinases from *Lipomyces starkeyi* and *Aspergillus arachidicola* have also been cloned and expressed in *Escherichia coli* (Bao *et al.*, 2019; Jiang *et al.*, 2019).

Applications of Inulinases

High Fructose Syrup Production

Inulin is abundantly stored in many plants such as chicory, Jerusalem artichoke, dahlia and dandelion (Table 1). Due to the abundance and renewability of this plant fructan, it can be readily utilized for generation of fructose and FOS for food, beverages and pharmaceutical industries (Singh and Singh, 2017a). Major applications of inulinases in diverse industries are compiled in Table 2.

Fructose is a low-calorie and generally regarded as safe (GRAS) sweetener having a two-fold higher sweetness index and half the calorific value compared to sucrose (Singh et al., 2017b; Kamble et al., 2019). Fructose production using traditional methods involves either sucrose hydrolysis by invertase into equimolar mixtures of glucose and fructose (Chen et al., 2016), or production of glucose-fructose syrup, using starch hydrolysis by glucoamylase and subsequent conversion into fructose by glucose isomerase. The maximum achievable yield by these methods is only 45%–50% of fructose in the syrup (Chen et al., 2016). In comparison to conventional methods of fructose generation from starch using α -amylase, glucoamylase and isomerase, fructose generation using exo-inulinases yields up to 90%–95% fructose from raw inulin sources (Hughes et al., 2017). These procedures also require purification of fructose using ultra-filtration and crystallization (Guthrie and Morton, 2000). In contrast, inulin is a linear polymer of fructose and therefore, fructose generation using fungal inulinases is a single step process. Biocatalytic hydrolysis of inulin by exo-inulinase to generate fructose units is considered as an efficient, direct, economic and eco-friendly approach (Singh et al., 2018).

Major exo-inulinase producers belong to the genera *Aspergillus*, *Fusarium*, and *Penicillium* and application of their enzymes has been reported to result in high fructose syrups from inulin (Rawat et al., 2015a; Magadum and Yadav, 2018). Among yeasts, *Kluyveromyces* spp. is known to be a prolific source of exo-inulinase (Liu et al., 2016; Bae et al., 2018).

Inulin rich plants, such as Jerusalem artichoke and dahlia are gaining increased industrial attention, because these are economical, abundant and renewable sources of this fructan. Exo-inulinases convert plant inulin into fructose, an easily fermentable monosugar, which can be used for production of a number of products such as citric acid, ethanol, butanol, biodiesel, and lactic acid (Fig. 4) (Gao et al., 2015).

Fructose generation from enzymatic hydrolysis of plant inulin is gaining interest due to its cost-effective generation using agro-wastes. Many plants listed in Table 1 have sufficient amounts of inulin, which yields fructose when hydrolyzed either chemically or by fungal inulinases. Enzymatic hydrolysis is preferable as it yields pure fructose syrup and indiscriminate products due to acid or alkali treatment are avoided. Both roots and stems of some inulin rich plants were used as raw material for fructose generation (Holyavka et al., 2018). *A. niger* was used for saccharification of *Agave tequilana* fructans to fructose (Huitrón et al., 2013). Alginate immobilized exo-inulinase from *A. niger* was tested for fructose generation from dahlia inulin and dandelion tap root extract in a packed bed bioreactor. Continuous generation of fructose (>90% w/w yield) from *Taraxacum officinale* tap root extract and chicory inulin using *A. niger* exo-inulinase in a packed-bed reactor has been demonstrated (Rawat et al., 2017b). Various inulin sources such as Jerusalem artichoke root, chicory root, asparagus root, dahlia tubers and agave juice have been used for enzymatic generation of fructose using fungal and yeast inulinases (García-Aguirre et al., 2009; Singh et al., 2018). Asparagus and chicory root extracts hydrolyzed by *Aspergillus tubingensis* inulinase in a batch reactor resulted in 14.25 g/L fructose generation (Trivedi et al., 2015) while kuth (*Saussurea lappa*) root powder upon treatment with *A. niger* inulinase in a continuous fermentation system produced 68 g/L of fructose (Yewale et al., 2013).

Production of Prebiotic Fructooligosaccharides

Fructooligosaccharides (FOS) are well known prebiotics as they have tremendous capacity to selectively nourish beneficial gut microbiota. Some FOS naturally occur in plants such as Jerusalem artichoke, dahlia with inulin, fructose and other sugars (Rawat et al., 2017b). Inulin type FOS or inulooligosaccharides (IOS), consist of fructose units linked with β -2,1 glycosidic linkages with a terminal glucose unit, while the other type is composed of only fructose (Fn or FOS) molecules linked by β -2,1 glycosidic linkages. FOS can be obtained either by hydrolyzing naturally occurring fructan (inulin) into oligofructose; Fn type FOS (DP > 9) by endo-inulinase, or by transfructosylation of sucrose into oligofructose containing terminal glucose; GFn type FOS (DP < 4) by fructosyltransferase (Ganaie et al., 2014; Bali et al., 2015; Choukade and Kango, 2019).

Several endo-inulinases have been reported from fungal strains among which endo-inulinase from *A. niger* is well explored and also commercially exploited to generate inulin type FOS (Kango and Jain, 2011; Li et al., 2013; Vallejo-García et al., 2019). Endoinulinase from *A. niger* has been reported to produce inulotriose (F3), inulotetraose (F4) and inulopentaose (F5) from inulin produced by the bacterium *Leuconostoc citreum*. The enzyme yielded 30 g/L of FOS and 10 g/L of free fructose in 4 h from 40 g/L bacterial inulin (Vallejo-García et al., 2019). Kawee-Ai et al. (2019) have reported that conversion of sucrose (300 g/L) to FOS (0.71 FOS/g substrate) using *A. niger* inulinase can be expedited by conducting the reaction under high pressure (300 MPa). An endo-inulinase from *A. arachidicola* generated DP3 and DP4 oligosaccharides at 60°C (Jiang et al., 2019). Inulinase from *L. starkeyi* produced FOS mixture containing 26% DP3, 34% DP4, and 23% DP5 oligosaccharides from 5% (w/v) inulin (Bao et al., 2019). A mixture of exo-inulinase prepared using *A. niger* and commercial endo-inulinase (Megazyme) in a ratio of 1:3 resulted in 33% hydrolysis of low DP agavins (from *Agave angustifolia*) at 60°C and generated 10% of different DP FOS with DP7 and DP8 as major products (Huazano-García and López, 2018).

Table 2 Applications of fungal inulinases in generation of value-added products

Applications	Organism	Enzyme	Product (s)	Yield	Reference
High Fructose Syrup (HFS)	<i>Aspergillus flavus</i> <i>Aspergillus terreus</i>	Exo-inulinase	HFS	–	(Das <i>et al.</i> , 2019b)
		Exo-inulinase	HFS	92% bioconversion of sucrose using Ca-alginate immobilized inulinase	(Magadum and Yadav, 2018)
	<i>Kluyveromyces marxianus</i>	Immobilized exo-inulinase on KU – 2 matrix cation-exchanger/ Adsorption	Fructose	–	(Holyavka <i>et al.</i> , 2019)
Single Cell Oil (SCO)	<i>Rhodotorula paludigena</i>	Inulinase	Mannitol esters of 3-hydroxy C14, C16 and C18 fatty acids with variable acetylation	48.5 g/L of polyol esters of fatty acids and 16.9 g/L of intracellular lipid in 156 h	(Wang <i>et al.</i> , 2019)
	<i>Yarrowia lipolytica</i> X2 <i>Y. lipolytica</i> X + N8	Inulinase Inulinase	Fatty acid C _{15:0} (0.28%), C _{16:0} (14.26%), C _{16:1} (10.06%), C _{17:1} (1.46%), C _{17:0} (0.27%), C _{18:2} (8.77%), C _{18:1} (53.10%), C _{18:0} (8.82%), C _{20:0} (0.42%), C _{22:0} (0.43%), C _{24:0} (2.14%),	42% (w/w) in 78 h 48% (w/w) in 78 h	(Shi <i>et al.</i> , 2018)
	Recombinant oleaginous yeast <i>Aureobasidium melanogenum</i>	Inulinase	C _{16:0} (29.95 ± 0.2%), C _{16:1} (2.13 ± 1.0%), C _{18:0} (6.06 ± 0.4%), C _{18:1} (35.58 ± 4.0%), C _{18:2} (25.98 ± 0.3%)	66% (w/w) in 120 h 0.12 g/g of consumed inulin	(Li <i>et al.</i> , 2019)
Oligosaccharides (IOS or FOS)	<i>Aspergillus niger</i>	Endo-inulinase (Novozym 960)	Inulotriose (F3), inulotetraose (F4), inulopentaose (F5)	approximately 30 g/L of FOS and 10 g/L of free fructose were produced from 40 g/L of bacterial inulin in 4 h.	(Vallejo-García <i>et al.</i> , 2019)
	<i>Y. lipolytica</i> recombinant strain	Endo-inulinase	DP 3–5 FOS	0.912 ± 0.012 g _{FOS} /g _{inulin} in 2 h	(Mao <i>et al.</i> , 2019)
	<i>Aspergillus arachidicola</i> <i>Lipomyces starkeyi</i>	Endo-inulinase Endo-inulinase	DP3 and DP4 DP 3–5	– 26% DP3, 34% DP4 and 23% DP5	(Jiang <i>et al.</i> , 2019) (Bao <i>et al.</i> , 2019)
Bioethanol	<i>Saccharomyces cerevisiae</i> <i>K. marxianus</i>	Exo-inulinase	Bioethanol	85.2 g/L in 72 h	(Khatun <i>et al.</i> , 2016)
		Exo-inulinase	Bioethanol	105 g/L at 37°C 97 g/L at 40°C	(Charoensopharat <i>et al.</i> , 2015)

Fig. 4 Metabolism of fructose generated by inulin hydrolysis and generation of various value-added products.

A number of fungi belonging to genera *Aspergillus*, *Penicillium*, *Fusarium*, *Arthrinium*, and *Kluyveromyces* have been shown to produce inulinase that generate inulooligosaccharides from chicory or Dahlia inulin (Rawat *et al.*, 2015a,b). Agavins or the fructans derived from Agave (*A. angustifolia*) have been exploited to generate branched fructooligosaccharides (*a*-FOS) using a commercial endo-inulinase from *A. niger* (Huazano-García and López, 2018). Cloning and overexpression of fungal inulinases has been successfully attempted in both bacteria and yeast. *A. arachidicola* endo-inulinase gene expressed in *E. coli* resulted in 88.4% IOS generation from 10 g/L inulin (Jiang *et al.*, 2019). Endoinulinase gene from *A. fumigatus* was cloned and over expressed in *P. pastoris* which resulted in the generation of IOS of DP 3, 4, 5, and >5 (Chen *et al.*, 2015). Recombinant endo-inulinase from *Fusarium oxysporum* was expressed in *P. pastoris* and used to generate FOS from inulin (8%) to 90.5 ± 5% DP 3–8 FOS (Yang *et al.*, 2016). Mao *et al.* (2019) developed a high inulinase yielding *Yarrowia lipolytica* strain expressing a fusion gene comprising inulin binding module from the bacterium *Bacillus macerans* and endo-inulinase from *A. niger*. The engineered *Y. lipolytica* generated FOS (DP3–5) with a yield of 0.912 ± 0.012 g_{FOS}/g_{Inulin} in 2 h.

Bioethanol Generation

Ethanol is the most popular biofuel that can be produced using monosugars generated from renewable plant biomass. A number of plants have been reported to contain inulin as their storage polysaccharide (Rawat *et al.*, 2017a). Fructose generation from inulin hydrolysis using exo-inulinase and its subsequent ethanolic fermentation by yeasts is viewed as a cheap and eco-friendly approach for bioethanol generation (Chi *et al.*, 2011). Coffee wastes containing pulp and mucilage were utilized to produce ethanol by *K. marxianus* Km7 strain by the catalytic action of inulinase, with a maximum ethanol yield of 10 g/L (Galindo-Leva *et al.*, 2016). Exo-inulinase producing yeasts, such as *K. marxianus* and *S. cerevisiae* are used for consolidated bioprocessing (CBP), in which hydrolysis of an inulin rich feedstock is coupled with fermentation of fructose to ethanol. Fructose is a readily fermentable sugar and is efficiently converted to ethanol by yeasts (Chi *et al.*, 2009). Plant biomass containing inulin such as Jerusalem artichoke tubers, Dahlia tubers and Asparagus roots can be utilized as raw material for fructose generation, which could further be utilized for large scale ethanol production. Simultaneous saccharification and ethanol generation of Jerusalem artichoke tuber powder using *K. marxianus* resulted in 104.83 g/L ethanol at 37°C (Charoensopharat *et al.*, 2015). Similarly, *S. cerevisiae* 6525

generated 84.3 g/L ethanol from 240 g/L dry powder of Jerusalem artichoke tubers in 72 h with a bioethanol yield of 0.453 or 88.6% (Wang *et al.*, 2015).

Single Cell Oil (SCO) Production

Biodiesel production from greener sources is gaining increasing interest and as a result, utilization of oleaginous SCO generators has gained considerable attention in recent years (Wang *et al.*, 2018). Microorganisms utilize plant sugars and produce oil in their cells similar to plant oils and are, therefore, suggested as alternate sources of oil (Liang and Jiang, 2013). Biodiesel is more advantageous as compared to traditional fuel due to its renewable, non-toxic and biologically degradable nature (Zeng *et al.*, 2017). Several yeasts, such as *Rhodotorula*, *Yarrowia*, *Aureobasidium*, *Candida*, *Cryptococcus*, *Trichosporon*, *Lipomyces*, *Papiliotrema*, *Rhodospiridium*, and *Pichia* have been reported to produce single cell oil (Li *et al.*, 2019). SCO production using lignocellulosic materials is comparatively expensive due to mandatory pretreatment. Inulin, on the other hand, can easily be converted into fructose monomers by the action of exo-inulinases, which can be further utilized by oleaginous yeasts for SCO accumulation in their cells. *Rhodotorula paludigena* produced 48.5 g/L of polyol esters of fatty acids mainly composed of mannitol esters of 3-hydroxy C14, C16, and C18 fatty acids with variable acetylation and accumulated 16.9 g/L of intracellular lipids from inulin in 156 h in batch fermentation (Wang *et al.*, 2019). An oleaginous yeast, *Y. lipolytica*, accumulated 48.3% (w/w) oil and produced 13.3 g/L dry cell mass in 78 h from inulin, while 50.6% (w/w) oil and 14.6 g/L dry cell mass was accumulated from Jerusalem tuber extract in 78 h (Zhao *et al.*, 2010b). *Aureobasidium melanogenum* 9–1 produced 28.5 g/L of crude heavy oils in the medium containing 120.0 g/L glucose. Interestingly, the strain also produced 30.2 g/L of crude heavy oils in medium containing 160.0 g/L inulin. A transformant of this strain expressing exo-inulinase from *K. marxianus* could yield 43.0 g/L of crude heavy oils and cell dry weight was 24.7 g/L in 120 h of fermentation (Xin *et al.*, 2017).

Citric Acid and Lactic Acid Production

Global citric acid production has reached 2 million tonnes in 2015 and is expected to increase by 3.7% annually (See Relevant Websites Section). It is mainly used as food acidulant to provide protection against oxidative deterioration of food flavoring agents (Rakicka *et al.*, 2019). One of the most important criteria for industrial production of organic acids is the use of low-cost substrates for economic production. These raw materials should be inexpensive, renewable and non-toxic for industrial application. In this regard, inulin containing plant biomass presents itself as a promising substrate for industrial production of organic acids. Citric acid (200 g/L) production from pure inulin using *Y. lipolytica* with a yield of 0.85 g citric acid per gram of inulin has been demonstrated (Rakicka *et al.*, 2019). Another strain of *Y. lipolytica* produced 105.2 g/L citric acid from 200 g/L pure inulin (Rakicka *et al.*, 2016), while another *Y. lipolytica* strain produced 84 g/L citric acid and 1.8 g/L of isocitric acid from 10% inulin in 214 h when grown in a 5 L batch fermenter (Liu *et al.*, 2013).

Single Cell Protein and Tequila Production

Single cell protein (SCP) has variety of applications in nutraceutical industries due to high protein and essential amino acid content. Recombinant *Y. lipolytica* expressing an exo-inulinase gene from *K. marxianus* origin accumulated 47.5% protein in a 4% inulin medium in 72 h (Cui *et al.*, 2011). *C. aureus* G7a and its mutant Z114 were found to accumulate 59.1% and over 61% total protein when grown on inulin rich Yacon extract for 45 h at 37°C (Zhao *et al.*, 2010a).

Tequila, a fermented product of blue agave (*A. tequilana*) is a Mexican beverage that originated in Jalisco, Mexico. This beverage is the distilled product of fermented fructan rich agave juice. Enzymatic hydrolysis of agave with inulinases is an environmentally friendly approach to obtain tequila from agave juice and inulinase from *A. niger* has been employed for this purpose (Huitrón *et al.*, 2013).

Immobilized Inulinases

Enzyme immobilization is one of the best approaches for their cost-effective application and achieving higher stability and efficiency under harsh industrial environment (Singh *et al.*, 2017c). Generally, inulin hydrolysis is carried out at or over 60°C to obtain high fructose yields and to avoid any microbial contamination. Immobilized exo-inulinase from *K. marxianus* on KU-2 matrix (a cation-exchanger) showed optimal activity at 70°C (Holyavka *et al.*, 2019). Another anion exchanger matrix, AV-17-2P, was used to immobilize *K. marxianus* inulinase and was reusable up to 10 times (each cycle of 20 min) with no significant loss in activity (Holyavka *et al.*, 2018). Glutathione reductase coated gold nanoparticles (GSHAuMNP) were also employed as covalent immobilization matrix to immobilize commercial inulinase resulting in 83% conversion of inulin with high amounts (98%) of fructose generation. The immobilized enzyme was recyclable upto 10 cycles (Mohammadi *et al.*, 2019). An exo-inulinase from *Aspergillus tamaris* was immobilized on kaolinite clay using glutaraldehyde as a cross-linker. The enzyme showed enhanced affinity towards the substrate and was thermostable at 65°C for 6 h (Garuba *et al.*, 2018). Immobilized inulinase from *A. niger* showed enhanced storage stability up to 28 days when immobilized on Eupergit® C matrix using bis[4(2-hydroxy-3-methacryloyloxypropoxy)phenyl] as cross-linker via sulfide and divinylbenzene cross-linking. The enzyme produced fructooligosaccharides ranging from DP2 to DP6 (Trytek *et al.*, 2015).

Conclusion

Fungal inulinases have received considerable interest among researchers for their role in food and nutraceutical industries in the production of HFS and prebiotic FOS. Inulinases have paved the way for value-addition of abundant inulin rich plant material e.g. conversion of Jerusalem artichoke tuber powder to SCO, organic acids, alcohol etc. The strategy of molecular cloning and heterologous expression of fungal inulinases in yeasts has allowed consolidated bioprocessing for simultaneous saccharification and fermentation of inulin into ethanol, citric acid, lactic acid etc. Current trends in fungal inulinases suggest that they have very high potential in exploiting plant inulin for generation of HFS and bioethanol.

Fungal Proteases: Current and Potential Industrial Applications

Aleksandrina Patyshakuliyeva, Netherlands Institute of Ecology, Wageningen, The Netherlands

Introduction

Filamentous fungi have been widely used for a long time as cell factories for the production of high value compounds, metabolites and enzymes. Particularly, fungi are known to produce a broad range of hydrolytic enzymes such as lignocellulose degrading enzymes, lipases and proteases. These enzymes are extensively studied and explored for various industrial applications. Proteases represent a large and complex group of enzymes that catalyze the hydrolysis of peptide bonds in proteins (López-Otín and Bond, 2008). They are structurally and functionally diverse and vary in their substrate specificity, catalytic mechanism, nature of their active site, stability, optimum pH and temperature (López-Otín and Bond, 2008). They are secreted by all living organisms and are involved in carrying out and regulating various complex biological processes and signaling cascades. They play an important role in processes such as cell growth, cell division, apoptosis, signal transduction, sporulation and germination, viral protein synthesis, protection against harmful peptides, degradation of incorrectly folded proteins and autolysis (Rao et al., 1998). The major role of extracellular proteases is in nutrition due to their involvement in the hydrolysis of proteinaceous substrates. The degradation of long polypeptides into smaller peptides and amino acids contributes to their uptake by the cell.

Besides their involvement in essential biological functions, proteases are used in numerous industrial processes representing the most dominant enzyme sales worldwide (Giansanti et al., 2016; Li et al., 2013a; Rao et al., 1998). Proteins are degraded enzymatically using proteases or chemically in industrial settings. Protein hydrolysates produced using chemical catalysts often contain undesirably modified amino acids. Moreover, chemical degradation is not environmentally friendly and can result in uncontrollable reactions. Using proteases avoids these disadvantages. Proteases have high reaction rates that can be easily controlled. They are also sustainable, highly specific and can be easily inactivated once the desired degree of modification is achieved (López-Otín and Bond, 2008; Rao et al., 1998). Therefore, production of proteases has gained interest in scientific and industrial communities.

Proteases obtained from animals, plants, and, particularly, microorganisms represent a large and important industrial section. Plant proteases include papain, bromelain, keratinases, and ficain (Rao et al., 1998). Their extraction is a time-consuming process and depends on many factors such as climate conditions, viability and availability of land. Examples of proteases from animal origin are trypsin, chymotrypsin, pepsin and rennin (Rao et al., 1998). These enzymes are produced at smaller quantities when compared to the production of proteases from plants and microorganisms. The use of animals as a source of proteases is dependent on availability of livestock and is regulated by ethical policies.

For the reasons mentioned above, microorganisms represent an excellent source of proteases and are main producers of commercially available proteases. The vast diversity, fast growth, easy to manipulate, and simplified downstream processing are advantages of using microorganisms for the economical and efficient bulk production of proteases in comparison with using plant or animal cells (Contesini et al., 2018; de Souza et al., 2015). Microbial proteases have a broad spectrum of industrial applications such as dairy and meat processing, brewing, detergents, leather and pharmaceutical industries. The commercial protease cocktail Alcalase was the first detergent protease which was initially obtained from a strain of the bacterium *Bacillus subtilis* (Chouyyok et al., 2005). Another example of a bacterial protease is a thermostable zinc endopeptidase thermolysin that is obtained from *Bacillus thermoproteolyticus* and has optimum catalytic activity up to 70°C and potential in the biopharmaceutical industry (Inouye et al., 2007; O'Donohue et al., 1994). Bacterial proteases show high reaction rate and temperature stability, while fungal proteases are diverse, substrate specific and effective over a wide pH range (Rao et al., 1998). Examples of fungal species reported to produce proteases include the ascomycetes *Aspergillus sojae* (Gerelt et al., 2000; Ke et al., 2018), *Aspergillus oryzae* (Gerelt et al., 2000; Yue et al., 2019) and *Penicillium chrysogenum* strain Pg222 (Benito et al., 2003; Omrane Benmrad et al., 2018; Zhu et al., 2009), and the zygomycete *Rhizomucor miehei* (Soltani et al., 2016; Sun et al., 2018).

In this chapter, proteolytic enzymes from filamentous fungi and their characteristics will be discussed in relation to their current and potential industrial applications including food, pharmaceutical and detergent industries, leather and fabric processing, waste management, and research practice. The focus is also on different classes of fungal proteases, their mode of action and their role in fungal physiology.

Fungal Proteases

Filamentous fungi are extensively studied for protease production because of their ability to grow on various substrates. Production of proteases by fungi is strain dependent and influenced by a wide range of factors including pH, carbon and nitrogen sources, temperature, aeration, requirement of metal ion, agitation, etc. (Rao et al., 1998). Based on the optimum pH, proteases can be grouped into acidic (pH 2.0–6.0), neutral (pH 6.0–8.0) and alkaline (pH 8.0–13.0) proteases (Rao et al., 1998; Sabotić and Kos, 2012). Acidophilic and alkalophilic fungi, often originating from high acidic or alkaline environments, are able to produce

Table 1 Main groups of proteases, their properties and examples of fungal sources

Class	Active site	Optimal pH range	Fungal source	Reference
Aspartic protease	Asp-Asp	3 – 5	<i>Endothia parasitica</i> <i>Mucor miehei</i> <i>Mucor pusillus</i> <i>Mucor bacilliformis</i> <i>Penicillium oxalicum</i>	(Sardinas, 1968) (Sternberg, 1972) (Zhang <i>et al.</i> , 2015; Tonouchi <i>et al.</i> , 1986) (Areces <i>et al.</i> , 1992; Venera <i>et al.</i> , 1997) (Hashem, 2000)
Serine protease	Ser-His-Asp/Glu	7 – 11	<i>Arthrobotrys oligospora</i> <i>Aspergillus clavatus</i> <i>Penicillium chrysogenum</i> <i>Tritirachium album</i> <i>Thermoascus aurantiacus</i>	(Minglian <i>et al.</i> , 2004) (Hajji <i>et al.</i> , 2007) (Omrane Benmrar <i>et al.</i> , 2018) (Yang <i>et al.</i> , 2016) (Li <i>et al.</i> , 2011)
Metalloprotease	Glu-Try	7 – 9	<i>Armillaria mellea</i> <i>Coprinopsis cinerea</i> <i>Microsporum canis</i> <i>Pleurotus ostreatus</i>	(Healy <i>et al.</i> , 1999; Kim and Kim, 1999, 2001) (Lilly <i>et al.</i> , 2008) (Brouta <i>et al.</i> , 2002) (Joh <i>et al.</i> , 2004; Nonaka <i>et al.</i> , 1997)
Glutamic protease	Glu-Asp	2 – 3.5	<i>Phanerochaete chrysosporium</i> <i>Talaromyces emersonii</i>	(Sims <i>et al.</i> , 2004) (O'Donoghue <i>et al.</i> , 2008)
Cysteine protease	Cys-His-Asp	2 – 3	<i>Botrytis cinerea</i>	(Liu <i>et al.</i> , 2019)
Threonine protease	Thr	6.5 – 7.5	The role is mostly unknown	

acidic and alkaline proteases, which have great potential in industrial applications. For instance, in the detergent industry where the pH of cleaning products usually ranges from pH 9.0–12.0, alkaline proteases are used (Maurer, 2004; Niyonzima and More, 2015a,b; Saeki *et al.*, 2007). Examples of fungal species that are able to produce alkaline proteases include the ascomycetes *Myceliophthora* sp. (Zanphorlin *et al.*, 2010), *Aspergillus tamarii* (da Silva *et al.*, 2018) and *Fusarium* sp. (Ueda *et al.*, 2007), and the zygomycete *Rhizopus oryzae* (Negi *et al.*, 2020). A number of fungi, e.g. the ascomycetes *Neurospora crassa* (Guo *et al.*, 2011), *A. oryzae* (Vishwanatha *et al.*, 2010; Yue *et al.*, 2019) and *Penicillium duponti* (Emi *et al.*, 1976), and the basidiomycetes *Phanerochaete chrysosporium* (Dass *et al.*, 1995) and *Trametes sanguinea* (Tomoda and Shimazono, 1964), produce acid proteases which are used in food industry, as digestive aids and have potential in ethanol production.

Besides being grouped by their activity under acidic, neutral, or alkaline conditions, proteases can be also divided into exopeptidases, i.e., aminopeptidases and carboxypeptidases that act on the N-terminus or C-terminus of the peptide chain, respectively, and cleave one or a few amino acids, and endopeptidases that target internal peptide bonds (López-Otín and Bond, 2008; Rao *et al.*, 1998). Based on the catalytic mechanism of proteases, they are classified into six classes: aspartic, cysteine, glutamic, metallo, serine, and threonine proteases (López-Otín and Bond, 2008; Rawlings *et al.*, 2010). To attack the peptide bond of the substrate, aspartic, glutamic and metalloproteases utilize an activated water molecule as a nucleophile, while in the cysteine, serine and threonine proteases, an amino acid residue (Cys, Ser, or Thr, respectively) located in the active site acts as the nucleophile (López-Otín and Bond, 2008; Rao *et al.*, 1998). The MEROPS database represents the biggest collection of known proteases, their inhibitors and protease peptide substrates, and it is constantly being updated (Rawlings *et al.*, 2016). Table 1 summarizes the main groups of proteases based on the mechanism of catalysis and shows examples of their fungal sources.

Genomic studies demonstrated that genes encoding aspartic, cysteine, serine and metalloproteases comprise > 75% of all genes encoding extracellular proteases in the genomes of fungi (Nguyen *et al.*, 2019). Interestingly, experiments with fungal pure cultures and genome analysis showed that aspartic proteases were the dominant proteases in the extracellular protease pool of most fungal species (Caldwell, 2005; Rineau *et al.*, 2015; Shah *et al.*, 2013; Theron and Divol, 2014; Vranova *et al.*, 2013). The pH range of aspartic protease activity is usually between pH 3 and 5 (Hsiao *et al.*, 2014; Kumar *et al.*, 2005; Vishwanatha *et al.*, 2010). Several genes encoding extracellular fungal aspartic proteases have been cloned and the corresponding enzymes purified for industrial use (Gomi *et al.*, 1993; Horiuchi *et al.*, 1988; Jarai *et al.*, 1994; Purushothaman *et al.*, 2019; Takenaka *et al.*, 2019; Tonouchi *et al.*, 1986; vanKuyk *et al.*, 2000).

Serine proteases have been also extensively studied in fungi, especially those which are involved in host-fungus interactions (Bagga *et al.*, 2004; Geremia *et al.*, 1993; Jashni *et al.*, 2015; Monod *et al.*, 2002; Reddy *et al.*, 1996; Williams *et al.*, 2003). For instance, subtilisin-like serine proteases are secreted by many fungal pathogens during penetration and colonization of a host (Bagga *et al.*, 2004; Jashni *et al.*, 2015; Ke *et al.*, 2018; Li *et al.*, 2010; Monod *et al.*, 2002). In industry, serine proteases are widely used as detergents (Vojcic *et al.*, 2015). They are also applied for research purposes such as protein degrading agents, e.g., during nucleic acid purification (Proteinase K from the basidiomycete *Tritirachium album*) (Yang *et al.*, 2016). Serine proteases purified from fungi are mainly neutral or alkaline proteases (Minglian *et al.*, 2004; Wang *et al.*, 2007; Zanphorlin *et al.*, 2010).

Metalloprotease is another class of proteases which plays an essential role in fungal pathogenesis (Yike, 2011). These enzymes require divalent metal ions (Mg^{2+} , Mn^{2+} , Co^{2+} , or Zn^{2+}) for their activity and are inhibited by compounds binding these metals,

Fig. 1 Current and potential industrial applications of fungal proteases.

such as the chelating agent ethylenediaminetetraacetic acid (EDTA). Zinc-dependent metalloproteases such as fungalsin are the most common metalloproteases in fungi. For instance, fungalsins from human and animal fungal pathogens promote pathogenicity by degrading structural proteins such as elastin and keratin (Brouta *et al.*, 2002; Markaryan *et al.*, 1994; Sirakova *et al.*, 1994). In plant pathogens, fungalsins act as a virulence factor, which is required for degradation of the plant chitinases and, consequently, promote infection (Ökmen *et al.*, 2018; Pan *et al.*, 2020; Sanz-Martín *et al.*, 2016). An unusually high number of fungalsins were found in the genome of the model basidiomycete *Coprinopsis cinerea*, a non-pathogenic fungus (Lilly *et al.*, 2008). The eight predicted *C. cinerea* fungalsins were compared with fungalsins from other fungi and further divided into two groups (Lilly *et al.*, 2008). Seven predicted *C. cinerea* fungalsins formed a group with similarity to fungalsins of the basidiomycete *Laccaria bicolor* (Lilly *et al.*, 2008), while one of them was most similar to fungalsins from the basidiomycete *Ustilago maydis* and the ascomycete *Aspergillus fumigatus* (Lilly *et al.*, 2008). However, the functions, specificity, and regulation of fungalsins in non-pathogenic fungi remain largely unknown. Interestingly, several research studies have also characterized and purified metalloproteases with fibrinolytic activity and potential use in medicine from various basidiomycetes (Healy *et al.*, 1999; Joh *et al.*, 2004; Kim and Kim, 1999, 2001; Nonaka *et al.*, 1997; Wu *et al.*, 2011). Most of the purified metalloproteases are neutral or alkaline proteases.

The majority of the studies on fungal proteases are focused on the above described aspartic proteases, serine proteases and metalloproteases. The least characterized classes of proteases in fungi are extracellular cysteine and glutamic proteases, and the role of fungal threonine proteases is mostly unknown. Based on the pH at which these proteases are active, cysteine and glutamic proteases are categorized as acidic proteases, while threonine protease as neutral proteases (Madala *et al.*, 2010; Rao *et al.*, 1998). Functionally characterized fungal cysteine proteases are intracellular enzymes, for instance, cysteine protease from the ascomycete *Botrytis cinerea* plays crucial roles in mycelial growth, conidiation, sclerotial development and virulence (Liu *et al.*, 2019). Glutamic proteases are a distinct class from the previously described proteases. A comparative genomics approach was used to evaluate the conservation and evolutionary distribution of glutamic acid protease encoding genes in 23 fungal genomes (Sims *et al.*, 2004). This study demonstrated that glutamic proteases were present in all tested ascomycetes. Moreover, a large number of glutamic proteases were also found clustered together in the basidiomycete *P. chrysosporium* genome (Sims *et al.*, 2004). In another research study, glutamic protease from the thermophilic fungus *Talaromyces emersonii* was isolated and characterized (O'Donoghue *et al.*, 2008). This protease had maximum hydrolysis at 50°C and pH 3.4, and its activity was essential for growth of *T. emersonii* (O'Donoghue *et al.*, 2008). Potential industrial applications of fungal cysteine, glutamic acid and threonine proteases have been poorly investigated in contrast to the aspartic proteases, serine proteases and metalloproteases.

Fungal Proteases in Industry

Proteases of fungal origin are used in a large variety of biotechnological applications, mainly in food industries such as brewing and cereal processing, cheese making, baking, production of protein hydrolysates (Liu *et al.*, 2018; Ozturkoglu-Budak *et al.*, 2016; Setoguchi *et al.*, 2019; Wang *et al.*, 2005). Fungal proteases also have extensive applications in pharmaceutical industry as potential drug targets, diagnostic biomarkers or as therapeutic agents. They are also envisaged to have potential in leather and fabric processing, waste treatment, bioremediation processes and detergent industry. Finally, they represent important tools for numerous research applications in molecular biology. Fig. 1 provides a summary of the current and potential applications of fungal proteases in industry.

The physical and chemical characteristics of fungal proteases have been explored and described in detail. Strains producing high amounts of proteases were isolated, studied through extensive screening, characterized, and further improved through genetic modifications (Jarai *et al.*, 1994; Liu *et al.*, 2018; Papagianni and Sergelidis, 2014; Setoguchi *et al.*, 2019; Sircar *et al.*, 2015; Starzyńska-Janiszewska *et al.*, 2015). A large number of protease-producing fungal strains belong to the Ascomycota and the Mucoromycota including *Aspergillus* (Liu *et al.*, 2018; Starzyńska-Janiszewska *et al.*, 2015; Takenaka *et al.*, 2019), *Penicillium* (Emi *et al.*, 1976; Papagianni and Sergelidis, 2014; Zhu *et al.*, 2009), *Fusarium* (Juntunen *et al.*, 2015; Ueda *et al.*, 2007), *Trichoderma* (Deng *et al.*, 2018; Zhang *et al.*, 2017), *Thermoascus* (Li *et al.*, 2011; Merheb-Dini *et al.*, 2009), *Rhizopus* (Hsiao *et al.*, 2014; Kumar *et al.*, 2005) and *Mucor* (Kangwa *et al.*, 2018; Tonouchi *et al.*, 1986). It has also been shown that proteases from the Basidiomycota have unique properties with potential in various applications (Inácio *et al.*, 2015). However, in comparison to the bacterial proteases, fungal proteases are less studied and commercially used (Tsiatsiani and Heck, 2015). Thus, with the wide diversity of fungi and their abilities to adapt to different carbon and nitrogen sources by secreting an arsenal of extracellular enzymes, the research of fungal proteases is an area that warrants more exploration.

Proteases for the Food Industry

The use of proteases in the food industry has a large variety of applications which are linked to the nutritional and functional value of the products. They play an essential role in modifying the functional properties of proteins during the cheese making process and the viscoelastic properties of dough in baking. Proteases are used in the brewing industry, processing of cereals, obtaining protein hydrolysates, production of seasonings and improvement of the quality of protein-rich food.

Dairy

The main application of proteases in the dairy industry is the coagulation of milk during the production of cheese. The processing of milk was earlier mostly performed by using milk-coagulating calf rennet which is a mixture of the proteases chymosin and pepsin (Rothe *et al.*, 1976). A rising demand for cheese production led to shortage of calf rennet and the increased ethical issues associated with its use by cheese manufacturing industries. Therefore, mining for alternative enzymes from microbial sources for milk clotting has been a focus for researchers and cheese producers. Fungal acidic aspartic proteases are extensively used in large-scale commercial settings gradually replacing calf rennet in cheesemaking process (Mandujano-González *et al.*, 2016). These proteases produced by fungal species such as *Mucor miehei* (Sternberg, 1972), *Mucor pusillus* (Tonouchi *et al.*, 1986; Zhang *et al.*, 2015), *Mucor bacilliformis* (Arecas *et al.*, 1992; Venera *et al.*, 1997), *Endothia parasitica* (Sardinas, 1968), and *Penicillium oxalicum* (Hashem, 2000) have been purified and their enzymatic properties have been explored in detail. Fungal proteases appear to be more proteolytic and heat-stable than calf rennet resulting in non-specific proteolytic activity which leads to a loss of casein fragments (Mandujano-González *et al.*, 2016). High levels and high thermal stability of proteases are associated with bitterness in cheese after storage (Habibi-Najafi and Lee, 1996). Therefore, comprehensive research has been performed to improve fungal proteases (Vishwanatha *et al.*, 2010; Zhang and Zhao, 2010; Yegin *et al.*, 2012; Zhang *et al.*, 2015). This resulted in the development of enzymes mixtures with low levels of nonspecific proteases and which are inactivated during pasteurization (Feijoo-Siota *et al.*, 2014).

Cow's milk also contains about 30 proteins which can potentially induce allergic reactions or sensitization (Tsabouri *et al.*, 2014). The main milk allergens are whey proteins and α s-casein (El-Agamy, 2007). Proteases are able to efficiently hydrolyze proteins and, consequently, eliminate these major milk allergens (Lee, 1992). Fungal proteases are increasingly used for this application (Ena *et al.*, 1995; Lakshman *et al.*, 2011). However, extensively hydrolyzed peptides have bitter taste which is a major drawback of using proteases (El-Agamy, 2007).

Baking

Fungal proteases play an important role in baking process. Wheat flour is a typical component of dough and contains insoluble protein gluten. Gluten determines functional properties of dough such as viscoelastic properties and facilitates dough to rise during the baking process (Heredia-Sandoval *et al.*, 2016). The addition of proteases that partially hydrolyze gluten can accelerate the dough making process by decreasing the mixing time of the dough and results in the higher loaf volumes (Rao *et al.*, 1998). A protease from *A. oryzae* has been used to modify gluten in wheat flour during the baking process (Rao *et al.*, 1998). It has been also shown that *A. oryzae* protease has potential to be used as an additive in the formulation of gluten-free bread, for example, bread made with rice flour. Treatment of rice flour with *A. oryzae* protease improved the characteristics of the dough (Hamada *et al.*, 2013). It had higher viscosity, slower sedimentation of the flour particles and increased loaf volume (Hamada *et al.*, 2013).

Brewing

Processing of cereals such as barley or rice is a fundamental part of brewing. It involves several enzymes with (hemi)cellulolytic and proteolytic activities. Cell wall components of cereals are degraded by cellulases and hemicellulases, while protein-based materials are degraded by proteases during the malting process. Proteases release and increase the amount of alpha-amino nitrogen which is important for the growth of yeast that performs the alcoholic fermentation. For instance, acid proteases from *A. oryzae* are used to hydrolyze proteins from the steamed koji rice during the fermentation of sake (Kitano *et al.*, 2002; Shindo *et al.*, 1998). Acid proteases from fungal origin have been investigated for their abilities to degrade proteins in the haze fraction

formed during production of various beverages. It has been demonstrated that the addition of a proline specific protease from *Aspergillus niger* during the fermentation phase of beer brewing prevented chill-haze formation in bottled beer (Lopez and Edens, 2005). Furthermore, acid proteases from *Aspergillus saitoi* are used to hydrolyze the proteins that cause turbidity during the production of fruit juices and alcoholic beverages (Sumantha et al., 2006).

Protein hydrolysate production

Proteins are essential elements in food and, when hydrolyzed, represent a valuable source of functional molecules. Protein hydrolysates generated by proteases are widely used as food additives. Animal derived proteins (gelatin, casein, whey proteins) and plant derived proteins (soy, rice, maize proteins) are sources of protein hydrolysates with potential application in the functional food industry. Bioactive peptides derived from proteolysis possess antioxidant, antihypertensive, antimicrobial, and immunomodulatory activities. Protein hydrolysates also react with other food elements and create various flavors. For example, the reaction between reducing sugars and amino acids called Maillard reaction enhances caramel-like flavors, soy sauce-like odors, umami and mouthful tastes and reduces bitterness (Li et al., 2013b; Lingnert and Eriksson, 1980; Liu et al., 2012). Protein hydrolysates are used in a variety of foods, such as soups, stock cubes, broth, savory sauces, canned meat and ready-made meals. Fungal proteases from species representing the genera *Aspergillus*, *Rhizopus*, and *Penicillium*, are extensively applied to produce protein hydrolysates for food and functional food industries (Agrawal et al., 2004; de Castro and Sato, 2014; Lima et al., 2015; da Silva et al., 2019a; Sparringa and Owens, 1999; Su et al., 2011).

Proteases for the Pharmaceutical Industry

Proteases are a major focus for therapeutic applications as potential drug targets, diagnostic biomarkers or as therapeutic agents (Turk, 2006). Common molds, in particular *Aspergillus fumigatus*, can cause life-threatening symptoms in patients with weakened immunological systems or asthma (Denning et al., 2014; Hohl et al., 2005). Serine proteases appear to play an important role in the development of these symptoms (Basu et al., 2018; Tai et al., 2006). For instance, serine proteases may induce epithelial barrier dysfunction in asthma through cytoskeletal rearrangements (Druey et al., 2020). Another example is an *A. fumigatus* alkaline serine protease found in patients diagnosed with cystic fibrosis which is a lung disease characterized by chronic progressive airway infection (Cowley et al., 2017). Research studies indicate that fungal protease activities may be used as potential drug targets to develop novel therapeutic agents for the treatment of infections caused by fungi to improve patient health (Cowley et al., 2017; Druey et al., 2020). *A. fumigatus* secreted proteases have also been investigated as novel diagnostic biomarkers for diagnosis of fungal infection (Kniemeyer et al., 2016; Moloney et al., 2016; Watson et al., 2011).

The wide diversity and specificity of fungal proteases make them a unique source in developing effective therapeutic agents. Fibrinolytic proteases are important enzymes that may act as thrombolytic agents in the therapeutic treatment of thrombosis (blood clotting) (da Silva et al., 2019b; Lee et al., 2005). The formation of fibrin, the main protein component of blood clots, and its adhering to the blood vessels' epithelial wall are responsible for cardiovascular diseases, such as high blood pressure, ischemic heart diseases, valvular heart disease and stroke (Corte et al., 2011). Fungi have been shown to be a good source of proteases with fibrinolytic activities and have increasingly attracted pharmaceutical and medical interests. Fibrinolytic proteases from several fungal species, for example, the zygomycete *Mucor subtilissimus*, the ascomycetes *A. oryzae* and *Fusarium* sp., and the basidiomycetes *Pleurotus ostreatus* and *Schizophyllum commune* have been reported (da Silva et al., 2019b; Liu et al., 2014; Lu et al., 2010; Nascimento et al., 2016; Shirasaka et al., 2012; Ueda et al., 2007).

Another application of therapeutic proteases includes digestive enzymes preparations. The use of digestive drugs is mainly directed at correcting enzyme efficiencies. Digestive enzyme preparation is a mixture of three enzyme classes: lipases, amylases and proteases. Proteases derived from species in the genus *Aspergillus* are widely used as a component of digestive preparations (Rao et al., 1998; Sugiura et al., 1976). For instance, acid protease and alkaline protease from *A. oryzae* are included in the Amano Enzyme protease preparation (Yang et al., 2017). *A. oryzae* proteases from this enzyme preparation were shown to be responsible for the bifidogenic effect in rats which may prevent against various disorders such as colon and liver diseases, allergies and insulin resistance (Yang et al., 2017).

Proteases for Leather and Fabric Processing

The main building block of leather are collagens, keratins, glycoproteins and lipids which are all enzymatically biodegradable. Therefore, enzymes play an important part in the leather processing industry (Thanikaivelan et al., 2004). Soaking, dehairing, bating, and tanning are principle steps of the leather processing (Thanikaivelan et al., 2004). The process of soaking is crucial to make the raw hide swell and restore its moisture. Alkaline protease treatment is used during this step to remove globular proteins and to hydrolyze non-collagenous proteins of leather. This results in improved water absorption and accelerated penetration of chemicals. Alkaline proteases are also widely applied in the dehairing process to enhance the degradation of the epidermal structure of the hide. Bating is a process where proteolytic enzymes hydrolyze and remove a non-collagen protein, which makes the leather flexible and elastic (Rao et al., 1998). Various combinations of microbial proteases together with trypsins have been used in leather processing. The potential use of fungal proteases from *Aspergillus flavus*, *A. tamarii* and *Aspergillus parasiticus* in leather processing has been demonstrated (Anitha and Palanivelu, 2013; da Silva et al., 2016; Malathi and Chakraborty, 1991). Application of proteases for soaking, dehairing and bating is more environmentally friendly and more efficient when compared with traditional methods which involve the use of hazardous chemicals.

In addition to the application of proteases in the leather processing industry, they also have a valuable role for the silk industry. Silk is formed by two proteins: sericin (22%) and fibroin (76%) (Ki *et al.*, 2009; Wang and Zhag, 2011). Fibroin filaments are the main component of a textile fiber. Sericin protein is a protective and gum gluing layer over the fibroin. Degumming is a removal of sericin during silk processing and plays a key role in achieving strength, softness and a typical shiny and elegant aspect in the finished fabric. This process consumes high energy and water and has an impact on the environment. Thus, application of proteolytic enzymes has gained a lot of attention in recent years. Several fungal proteases have been investigated to develop enzyme-based silk degumming process (Eom *et al.*, 2020; Freddi *et al.*, 2003; More *et al.*, 2013).

Other Applications of Fungal Proteases

Proteases of fungal origin have potential in a variety of industrial applications. In recent years, fungal proteases gained an interest in industrial portentous waste management in industries like poultry, fishery, and leather (Hathwar *et al.*, 2011; Majumder *et al.*, 2015). For instance, poultry-processing factories produce millions of tons of feathers annually as a waste product (Rodrigues Marcondes *et al.*, 2008). The recalcitrant and fibrous protein β -keratin is a main component of feathers, therefore, keratinolytic enzymes produced by fungi may have an important role in feather decomposition. The ascomycete fungi *Alternaria tenuissima*, *Acremonium hyalinulum*, *Curvularia brachyspora*, *Beauveria bassiana* and *Chrysosporium keratinophilum*, and the basidiomycete *Termitomyces clypeatus* showed high keratinolytic activities and have potential use in biotechnological processes involving keratin hydrolysis (Majumder *et al.*, 2015; Rodrigues Marcondes *et al.*, 2008; Singh, 2002). Furthermore, fungal proteases may contribute significantly to the reduction of wastewater generated by distillery and agricultural industries (Morimura *et al.*, 1994; Salgado *et al.*, 2016).

The use of proteases in the detergents is the most dominant industrial application of proteases. These proteases are mainly derived from bacterial sources. The most characterized and commercialized for use in detergents are alkaline serine proteases subtilisins produced by *Bacillus licheniformis*, *Bacillus pumilus* and *Bacillus subtilis* and high alkaline proteases from *Bacillus clausii* and *Bacillus halodurans* (Rao *et al.*, 1998). Several studies have demonstrated that fungal alkaline proteases were also suitable for inclusion in detergent composition (Hajji *et al.*, 2007; Niyonzima and More, 2015a,b; Omrane Benmradi *et al.*, 2016).

Proteolytic enzymes also have applications in life sciences, particularly in molecular biology. They are used in peptide synthesis, cell isolation and tissue dissociation, cell culturing, antibody fragment production, structure-function relationship elucidation and nucleic acid isolation (Moriyama, 1987; Mótýán *et al.*, 2013; Rao *et al.*, 1998). The most widely used proteolytic enzyme in nucleic acid purification is the Proteinase K obtained from the basidiomycete fungus *T. album* (Dattagupta *et al.*, 1975; Yang *et al.*, 2016).

Conclusion and Future Prospective

Proteases are a unique class of enzymes involved in diverse physiological, biochemical and regulatory processes in all living organisms and represent immense commercial importance. Microorganisms are a preferred source of proteases because of their fast growth, accessibility to genetic manipulation and easiness in cultivation. Microbial proteases have been extensively used in detergent and food industries, and as therapeutic agents. Fungi possess a wider variety of proteases than bacteria. A common source of commercially available fungal proteases is *A. oryzae* which is able to produce acid, neutral, and alkaline proteases. Fungal proteases have broad substrate specificity and are active over a wide range of pH. Proteases of fungal origin have a large variety of biotechnological applications. They are used in food industries including brewing and cereal processing, cheese making, baking and production of protein hydrolysates. Fungal proteases are also applied in pharmaceutical industry where they are used as potential drug targets, diagnostic biomarkers or as therapeutic agents. Moreover, they have also found their use in leather and fabric processing and in many research applications particularly in the field of molecular biology. Many studies have also shown that fungal proteases have potential in waste treatment, bioremediation processes and detergent industry. The use of proteases for commercial applications is recognized as sustainable and an environmentally friendly technique.

This chapter provided an overview of the applications of fungal proteases (Fig. 1). Hydrolysis of proteins by fungal extracellular proteases for their growth, reproduction, sporulation and germination presents a good example of the implementation of a diverse and efficient fungal system into a well-designed industrial process. Use of fungal proteases for various applications has a long history and presents great importance for human society. Since we are moving towards a biobased renewable and sustainable society, these applications will certainly expand and will grow exponentially in the future. Proteolytic enzymes from fungal origin has already implemented in many industries, however the ongoing search for new and better protease from fungi, assisted by developing technologies, promises to provide more specific, thermostable and versatile proteases.

Large number of genome data generated from advanced post-genomics era and constantly increasing number of fungal genomes indicate that fungi possess high genetic potential with respect to the putative genes encoding proteases (Grigoriev *et al.*, 2014; Iqbal *et al.*, 2018; Muszewska *et al.*, 2017). While usually only well-studied protease producing fungi (e.g. *A. oryzae*, *A. niger*) were used as enzyme factories, currently many other fungal species have been demonstrated to have high potential in producing proteases suitable for many industrial applications (da Silva *et al.*, 2019a,b; Liu *et al.*, 2014; Nascimento *et al.*, 2016). Fungal genomes can be explored for novel proteases and their activities, but can also be mined for orthologous enzymes from related fungi that may have favorable properties.

The exploitation of fungal biodiversity and the discovery of new fungal strains with abilities to produce high level of proteases has been a great deal of interest in the biotechnological potential of these enzymes. For example, exploring new fungal strains that inhabit harsh environments such as extreme temperatures (hot springs and the Arctic), extreme pH (acidic or alkaline), high pressure, and high salinity. Fungi from these environments have adapted to thrive in these extreme ecological niches. As a result, they are able to produce unique enzymes that are active and stable under harsh conditions in which mesophilic enzymes could not survive. Such unique proteases have a great economic potential in many industrial processes, including agricultural, chemical, food and pharmaceutical applications.

The development of screening technologies, computational design, synthetic biology, and crystallography will allow characterization, engineering and production of proteases with tailored and improved physicochemical properties. It will increase the future potential for their current and novel applications that are faster, more accurate, specific and environmentally friendly.

Introduction

Phytic acid (*myo*-inositol hexakisphosphate) or phytate in its salt form is the main organic storage form of phosphorus (60%–80% of total) in plant tissues such as legumes, cereal grains, oilseeds, and pollen (Lott *et al.*, 2000; Fig. 1). Phytic acid acts as an anti-nutritional factor because of its ability to chelate cations, like Ca^{2+} , Zn^{2+} , Fe^{2+} and Mg^{2+} , and make them unavailable, to form complexes with starch and proteins that interferes with their digestion, and to inhibit the activity of digestive enzymes (Harland and Morris, 1995).

Phytase (*myo*-inositol hexakisphosphate phosphohydrolase) catalyzes the removal of phosphate from phytic acid or its salts (phytates) in a stepwise manner by cleaving five of the six phosphates (Wyss *et al.*, 1999; Konietzny and Greiner, 2002). The first reports of phytase activity from rice grains (Suzuki *et al.*, 1907) and an ascomycetous fungus *Aspergillus niger* (Dox and Golden, 1911) were published more than 100 years ago. Phytases are generally classified based on their structure and catalytic mechanism of cleavage of the phosphate from phytic acid as Histidine Acid Phosphatases (HAPs), β -propeller phosphatases/alkaline phytases (BPPs), purple acid phosphatases (PAPs), and dual-specificity phosphatases/protein tyrosine like phosphatases (DSPs/PTLPs). HAPs have been reported in numerous fungi such as *Cladosporium* sp., *Aspergillus niger*, *A. awamori*, *Fusarium oxysporum* and *Debaryomyces castellii* (Gontia-Mishra *et al.*, 2014; Jatuwong *et al.*, 2020). The structure of BPPs is similar to a six-bladed propeller (Ha *et al.*, 2000); these are alkaline phytases active at pH > 7.0 and found mainly in bacteria. Recently, the first alkaline fungal phytase was reported from *Arthrobotrys oligospora* (Hou *et al.*, 2020). PAPs belong to a special group of acid phosphatases (APases), which hydrolyze phosphate from phosphomonoesters and anhydrides with an optimum pH below 7.0 (Schenk *et al.*, 1999). They are most widespread in plants and also found in bacteria, fungi, and animals (Gontia-Mishra and Tiwari, 2013). PTPLP, also known as cysteine phytase, has the CX5R (S/T) domain in their active center, which participates in hydrolysis and are active in the pH range between 4.0 and 6.0. PTPLPs were first isolated from bacteria like *Selenomonas ruminantium* and *Megasphaera elsdenii*, which dwell in the rumen of ruminants (Puhl *et al.*, 2008, 2009). Recently there is also a report of neutral phytase from *Penicillium* sp. C1 (Ya-nan *et al.*, 2020).

Depending on the carbon atom where phosphate hydrolysis is initiated, phytases have also been classified as 3-, 5-, and 6-phytases (Mullaney and Ullah, 2003; Sun *et al.*, 2017). The 3-phytases (EC 3.1.3.8), which begin the hydrolysis from the phosphate group on C3 atom of phytic acid, are present in many bacterial and fungal species, while the 6-phytases (EC 3.1.3.26), which first hydrolyze the bond on C6 position, are present in plants and *Escherichia coli*. The 6-phytases perform complete dephosphorylation of the substrate, whereas the final product of hydrolysis with 3-phytases is *L*-*myo*-inositol-2-phosphate (Wodzinski and Ullah, 1996; Wyss *et al.*, 1999). 5-Phytases (EC 3.1.3.72), which start the reaction from the cleavage of the phosphate on C5, have also been identified, for example in the bacterium *Selenomonas* (Puhl *et al.*, 2008).

In nature, phytases are produced in a wide range of plant and animal tissues, and microbes (Vohra and Satyanarayana, 2003). Of immense commercial significance (reduction of phytate in foods and feeds, aquatic pollution abatement, soil amendment and therapeutics) are phytases from filamentous fungi such as *Aspergillus*, *Myceliophthora*, *Mucor*, *Penicillium*, *Rhizopus* and *Trichoderma* (Dailin *et al.*, 2019). A phytase from *Aspergillus ficuum* NRRL 3135 has been most commonly used commercially (Chelius and Wodzinski, 1994). Two methods of fermentation, Solid State Fermentation (SSF) and Submerged Fermentation (SmF), are employed for the production of fungal phytases (Han *et al.*, 1987; Shivanna and Venkateswaran, 2014). In the most common method, SSF, agricultural residues and other cheap plant biomass substrates like citrus peels, wheat bran, wheat straw, soybean meal and rice bran are used for the production of phytases from filamentous fungi such as *Aspergillus flavus*, *A. ficuum*, *A. niger*, *Thermomyces lanuginosus* and *Myceliophthora thermophila* (previous name *Sporotrichum thermophile*) (Singh and Satyanarayana, 2006; Awad *et al.*, 2014; Huang *et al.*, 2018). Using SmF, phytases can be produced from *Aspergillus carbonarius*, *A. fumigatus*, *A. niger*, *A. oryzae*, *Cladosporium* spp.,

Fig. 1 Structure of phytic acid showing six phosphate groups bound to cations and protein.

Mucor piriformis, *Rhizopus oligosporus* and *M. thermophila* (Howson and Davis, 1983; Singh *et al.*, 2011). Yeasts such as *Arxula adenivorans*, *Candida krusei*, *Pichia anomala* have also been reported to possess phytase activity (Kaur *et al.*, 2007; Olstorpe *et al.*, 2009). Phytase from the yeast *Pichia anomala* has been produced in submerged fermentation using Yeast extract-Peptone-Dextrose (YPD) medium (Vohra and Satyanarayana, 2002a) and cane molasses medium (Kaur and Satyanarayana, 2005).

In order to study their biochemical properties as well as structural and functional relationships, various chromatographic methods have been employed to purify phytases (Vohra and Satyanarayana, 2002b; Singh and Satyanarayana, 2009; Ranjan and Satyanarayana, 2016). Thermostability of phytase is desirable so that it can withstand temperatures as high as 70–90°C during the feed pelleting process (Doyle and Erickson, 2006; Dersjant-Li *et al.*, 2015). Resistance to proteases and broad range pH stability are important to withstand conditions in the gastrointestinal tract (Walton and Gray, 1979; Schroder *et al.*, 1998). Fungal phytases are active in the optimum temperature range of 37–67°C. Most fungal phytases are active at acidic pH in the range of 2.0 and 6.0 and belong to a class of HAPs (Vohra and Satyanarayana, 2003; Singh *et al.*, 2011), but phytases of some fungi such as the basidiomycete *Agaricus bisporus* and mucoromycete *Rhizopus microsporus* var. *microsporus* have optimum activity at pH 5.0–8.0 and 9.5, respectively (de Oliveira Ornela and Guimaraes, 2019). A phytase from *P. anomala* is optimally active at 60°C and pH 4.0 (Vohra and Satyanarayana, 2001). This enzyme is highly thermostable and acid stable, with a $T_{1/2}$ of seven and eight days at 60°C and pH 4.0, respectively, thereby suggesting its applicability in animal feeds (Vohra and Satyanarayana, 2002b).

The first recombinant phytase was produced by expressing the *phyA* gene of *A. fumigatus* in *A. niger* (Rebello *et al.*, 2017). The recombinant phytase was highly thermostable and remained active over a wide pH range. A phytase gene from the thermophilic fungus *M. thermophila* was cloned and expressed heterologously in *E. coli* and *Pichia pastoris* (Ranjan *et al.*, 2015; Singh *et al.*, 2018; Maurya *et al.*, 2017). The phytase from the yeast *P. anomala* was successfully over-expressed heterologously in other yeasts like *Hansenula polymorpha* and *P. pastoris* (Kaur *et al.*, 2010; Joshi and Satyanarayana, 2014).

Improvement in the enzyme characteristics of phytases has extensively and successfully been achieved using enzyme engineering (Chen *et al.*, 2015). Amelioration of phytase thermostability, specific activity, pH stability and protease resistance can be achieved by protein engineering. As mentioned before, stability of phytase at high temperatures is desirable to withstand feed pelleting conditions (Doyle and Erickson, 2006; Dersjant-Li *et al.*, 2015). In order to withstand conditions in the gastrointestinal tract, phytase must be stable in a broad pH range with a high specific activity (Schroder *et al.*, 1998). Hence, protein engineering has been extensively used to enhance thermostability of HAP, a commercially very important phytase. Improved thermostability of *A. niger phyA*, *E. coli appA* and *appA2*, and *A. fumigatus* phytase has been attained by protein engineering methods such as protein glycosylation, random mutation and site-directed mutagenesis (Mullaney *et al.*, 2010; Vasudevan *et al.*, 2019). In view of the multifarious applications of fungal phytases (Fig. 2), this review focuses on the potential biotechnological applications of these enzymes.

Applications of Phytases

Applications in Foods and Animal Feed

The most important biotechnological application of phytases is in the nutrition of monogastric animals and humans. Monogastrics are not able to breakdown phytates to liberate inorganic phosphorus due to lack of phytase, thus preventing their

Fig. 2 Multifarious applications of Fungal Phytases.

assimilation and concomitant reduction in the anti-nutrient phytate content of foods and feeds. The supplementation of phytase has, therefore, emerged as one of the most attractive and effective additives in foods and feeds.

Foods

The presence of phytates in plant-based foods, including flours, is well documented (Greiner and Konietzny, 2006). A large part of our global population tends to suffer from mineral (mainly, iron and zinc) deficiencies due to the ingestion of phytate rich plant diets (Bentley *et al.*, 1997; Tatala *et al.*, 1998). Studies in humans have conclusively shown that iron and zinc absorption from a meal corresponds inversely to its phytate content (Nävert *et al.*, 1985). The dietary phytase gets inactivated during cooking, resulting in poor phytate digestion that affects mineral absorption in the small intestine. Various food processing and preparation methods, like germination, soaking, cooking and fermentation, lead to only a partial reduction in the phytate content of the processed materials.

Phytases have been found to be useful as a food additive during fermentation, food processing and bread making, where they play an important role in human nutrition by degrading phytate during the processing as well as in the gastrointestinal tracts. During bread making, phytase improves proofing time, volume, and crumb structure. A phytase from *A. niger* is used in making dough that results in enhanced degradation of phytates (Turk and Sandberg, 1992), better iron absorption in humans (Sandberg *et al.*, 1996), increased bread volume as well as improved crumb texture (Haros *et al.*, 2001). Rosell *et al.* (2009) reported that *A. niger* phytase could be used in the frozen storage of bread to overcome the detrimental effects of bran on the mineral bioavailability. When bread was supplemented with a phytase of the thermophilic ascomycete *M. thermophila*, improvement in the bread quality and reduction in phytate content was reported (Singh and Satyanarayana, 2008a). This phytase has been shown to release inorganic phosphate from calcium, magnesium and cobalt phytates (Singh and Satyanarayana, 2010), and effectively dephytinize sesame oil cake and soymilk (Singh and Satyanarayana, 2006, 2008b). There are several studies on phytase activity in baker's yeast (Greiner *et al.*, 2001; Haraldsson *et al.*, 2005), whereby the researchers have emphasized the role of yeast phytase in bread making. During whole meal bread making, reduction in phytate levels were attained due to the activities of both wheat and yeast phytases (Turk *et al.*, 1996). The use of high yeast levels and fermentation times have been suggested to result in high-fiber bread with lower phytate content (Harland and Harland, 1980). Turk *et al.* (2000) studied two commercial strains of baker's yeast with the ability to express phytase activity and reported that they could rapidly degrade all the *myo*-inositol hexakisphosphate within 24 h. A native high-phytase *S. cerevisiae* strain has been suggested to be suitable for the production of food-grade phytase and for the direct use in food production (Veide and Andlid, 2006). The supplementation of whole wheat dough with a *P. anomala* phytase that was over-expressed in *P. pastoris* resulted in effective dephytinization of bread without any change in texture (Joshi and Satyanarayana, 2015a).

Apart from bread, phytases from fungi have also been used for reducing phytates from other plant derived foods. The level of phytic acid in *Icacina mannii*, a shrub used as a source of starch-based food during periods of famine in Africa, was reported to reduce 90% after six days of fermentation with *S. cerevisiae* (Antai and Nkwelang, 1998). Chapathi, the traditional unleavened flat bread that contains phytic acid and is prepared from whole wheat flour is the staple food in parts of India and some surrounding Asian countries. A mutated strain of the yeast *Candida versatilis* was used for the preparation of chapathi dough with up to 45% reduced phytic acid level (Bindu and Varadaraj, 2005). The purified recombinant phytases from *M. thermophila* and *P. anomala* were also useful in dephytinization of Indian baked breads Tandoori and Naan (Ranjan *et al.*, 2015; Joshi and Satyanarayana, 2015a). The phytase from *S. cerevisiae* MTCC 5421 efficiently dephytinized pearl millet flour (94%), and completely refined wheat flour as well as removed phytate from wheat-based (Naan) and pearl millet-based (Rabadi) fermented products (Roopashri and Varadaraj, 2015). Similarly, baker's yeast as a phytase source for reduction in phytic acid content in Tarhana, a traditional Turkish fermented and dried cereal food, was investigated (Bilgicli *et al.*, 2006).

Filamentous fungi commonly used in oriental food fermentation have been examined for their ability to produce phytase. Tempeh, a popular oriental fermented food made from soybeans, is inoculated with *Rhizopus oligosporus* in the koji process, where the fermentation improves the digestibility, vitamin content and flavor of soybean (Fardiaz and Markakis, 1981). Since phytate binds to proteins, protein isolates from soybeans are rich in phytate. Thus, phytases can be applied in the production of phytate-free soybean milk because of a high level of phytate (0.56%) in soymilk (Anno *et al.*, 1985; Khare *et al.*, 1994). The cell-bound phytase of *P. anomala* effectively dephytinized soymilk (Kaur and Satyanarayana, 2010). Besides dephytinization, the recombinant *P. anomala* phytase also fractionated allergenic glycinin from soy protein, which can be potentially useful for producing specialty foods for people allergic to specific components of soy protein (Joshi and Satyanarayana, 2014). The role of an *A. ficuum* phytase in legume dephosphorylation has also been investigated. It was shown to result in 78% reduction in phytate content of soybean meal after 15-h treatment (Han and Wilfred, 1988).

Animal feeds

Animal feeds, mainly hog and poultry diets, are plant based, and approximately two-thirds of the phosphorus of feedstuffs is in the form of phytate phosphorus (Tyagi *et al.*, 1998). Under most dietary conditions, this phytate phosphorus is unavailable to the monogastric animals (Nelson, 1967), and therefore inorganic phosphate supplementation is required, which adds to the cost of the feed due to the limited rock phosphorus supplies. Moreover, the unutilized phytate is excreted in the manure that causes problems in terms of phosphorus pollution. The phytates also chelate several important minerals, thereby reducing their availability to the animals. Phytases are therefore incorporated into the feed of non-ruminants or monogastric animals. Besides reducing the need of phosphorus supplementation and making trace minerals available, the degradation of *myo*-inositol hexakisphosphate yields *myo*-inositol, an important growth factor. This improves the digestibility and the nutritional value of the feeds, besides enhancing

growth rate of monogastric animals and mitigating the level of phosphorus excretion, thus minimizing the chances of environmental pollution. The nutritional value as well as the environmental significance of the use of fungal phytases in releasing phosphorus from plant-based animal feeds has been well documented (Kaur *et al.*, 2007; Singh and Satyanarayana, 2015).

Based on *in-vitro* feed experiments, it has been found that phytases with broad substrate specificity, for example the acidic phytases from *A. niger* and *A. terreus*, are better than those with narrow substrate specificity for animal nutrition (Wyss *et al.*, 1999). An ideal phytase for the poultry feed industry would be the one that withstands acidic pH and protease enzymes in the stomach and small intestine where phosphorus absorption takes place, cost-effective in production, and resistant to elevated temperatures (from 65 to 80°C) that are encountered during feed pelleting (Lei and Stahl, 2001). The most widely used phytases in animal feeds are HAPs. Supplemental phytase improves calcium, zinc, and iron utilization by animals (Lei *et al.*, 1993; Jondreville and Dourmad, 2005). Several feed trial experiments with poultry as well as swine have confirmed the possibility of replacing inorganic phosphorus (Pi) supplementation by using microbial phytase in phytate-rich diets for monogastric animals, and it has been reported that 500–1000 units of phytase can replace approximately 1.0 g Pi supplementation and reduce the total phosphorus excretion by 30%–50% (Yi *et al.*, 1996; Kemme *et al.*, 1997).

The phytase from *Aspergillus* was the first one studied to reduce the phytate content in poultry feeds (Nelson *et al.*, 1968, 1971). However, it was not until 1991 that the first phytase feed enzyme became commercially available. The *A. niger* phytase under the trade name of Natuphos (BASF) was approved for use as a feed additive in a number of Asian, European and North and South American countries, including Canada and the United States (Wodzinski and Ullah, 1996). There are various studies conducted on application of *A. niger* phytases in animal feeds. For example, the addition of *A. niger* phytase to maize and soybean meal-based diets led to improvement in growth and bone mineralization in broiler chicks with better relative retention of phosphorus and calcium (Ahmad *et al.*, 2004). Similarly, supplementing diets of pigs with *A. niger* phytase resulted in increased body weight and higher phosphorus content in their bones (Sands *et al.*, 2009). The waste tea fungal biomass produced during black tea fermentation, containing various nutrients and phytase, was supplemented as a dietary ingredient for broiler chicks, which led to increased feed consumption and body weight (Murugesan *et al.*, 2005). The phytase from *A. niger* van Teighem efficiently hydrolyzed phytate phosphorus in several commercial livestock feeds (Vats *et al.*, 2009). There was enhanced growth performance of broilers whose phosphorus-deficient diets were supplemented with phytase from *A. niger* and evaluated till 35 days after hatching (Srikanthithasan *et al.*, 2020). Very recently, a novel fungal beta-propeller phytase has been reported from the nematophagous fungus *Arthrobotrys oligospora* with a potential application in animal feed, based on its utility in releasing phosphorus from soybean meal and minerals from durum wheat and finger millet flour (Hou *et al.*, 2020).

The phytase from the yeast *Saccharomyces castellii* CBS 2863 successfully reduced the amount of phytate content in wheat bran and glandless cotton flour, thus proving the strain's efficacy in the pretreatment of animal feeds (Segueilha *et al.*, 1993). Matsui *et al.* (2000) reported that dietary yeast phytase improved bioavailability of phosphorus in growing pigs. However, its efficacy was less than that of *A. niger* phytase. The supplementation of cell-bound phytase of *P. anomala* in the feed of broiler chicks resulted in their improved growth, better phosphorus retention in their body and reduced excretion of phosphorus in the feces (Vohra and Satyanarayana, 2003), and was found to be economically viable as a chick feed supplement (Vohra *et al.*, 2006).

Following first commercialization attempts by Gist-Brocades Europe (1993–1994), several companies, like Alko Inc (Finland), Alltech (USA) and BASF (USA), started the industrial scale production of phytase marketed under the trade names Finase, Allzyme and Natuphos, respectively, and successfully utilized them in feed applications. All these originated from filamentous fungi. The Food and Drug Administration (FDA) of USA has provided phytase preparations with GRAS (Generally Regarded As Safe) status (Wodzinski and Ullah, 1996). The production of phytases at industrial scale is expensive, which limits their widespread use as a feed additive.

Phytases from transgenic plants and animals

Generating transgenic plants and animals expressing microbial phytase is a novel way to enzymatically reduce the phytate content in feed and food. By overexpressing mainly HAP encoding (Lung *et al.*, 2005) genes, several phytase-transgenic plants have been created (Mullaney *et al.*, 2000). Such plants aid in reducing phytic acid in seeds and grains used for animal and human consumption. The high phytase activity in fodder breaks down phytate, thereby facilitating the assimilation of phytate phosphorus from the fodder (Ige *et al.*, 2010). This approach also liberates the chelated metal ions like iron and zinc from phytate, thus making them available for absorption by humans (Lung *et al.*, 2005). There are several reports on the expression of phytase in transgenic plants. A comprehensive list of transgenic phytase crops and source of enzyme along with their experimental results is presented in Table 1. In most of these cases, mainly *phyA* from *A. niger* was expressed in the transgenic plants meant for feed additives. An improved growth rate resulted from supplementation of broiler diets with transgenic seeds (Pen *et al.*, 1993). Hamada *et al.* (2005) reported high-level expression of *Schwanniomyces occidentalis* phytase in transgenic rice plants, which could be stored as silage without any loss of activity until use as a feed additive (Hamada *et al.*, 2006). Based on these reports, the production of phytase through bio-farming using transgenic technology seems to be a promising approach.

The *appA* gene from *E. coli* was overexpressed in the salivary gland of pigs to generate the best-known phytase-transgenic animal, Enviropig (Golovan *et al.*, 2001a). This novel technology led to a 75% reduction in fecal phosphorus excretion in these animals. Thus, the activation of phytases in the saliva of transgenic animals facilitated the assimilation of phytates from the fodder. On similar lines, phytase-transgenic animals including fish, such as the Japanese medaka (*Oryzias latipes*) (Hostetler *et al.*, 2005), and mice (Golovan *et al.*, 2001b) have been developed. These studies suggested the possibility of developing poultry varieties with improved phytate digestion.

Table 1 Transgenic phytase crops and their sources

Phytase source	Type of phy gene	Plant system	Achievement	References
<i>Aspergillus awamori</i>	<i>phyA</i>	Soybean	Improved thermostability	Gao <i>et al.</i> (2007)
<i>Aspergillus ficuum</i>	<i>phyA</i>	Alfalfa	Alternative to commercial phytase	Ullah <i>et al.</i> (2002)
	<i>phyA</i>	Potato	Alternative to commercial phytase	Ullah <i>et al.</i> (2003)
	<i>AphyA</i>	Soybean	Improved phosphorus absorption efficiency	Li <i>et al.</i> (2009)
	<i>phyA</i>	Tobacco	Proved to be equal to commercial phytase	Ullah <i>et al.</i> (1999)
<i>Aspergillus fumigatus</i>	<i>fphyA</i>	Tobacco	Showed thermostability	Wang <i>et al.</i> (2007)
	<i>phyA</i>	Wheat	Broiler growth improved	Brinch-Pedersen <i>et al.</i> (2006)
<i>Aspergillus japonicus</i>	<i>phyA</i>	Wheat	Increased bioavailability of iron and zinc in grains, enhanced phosphorus uptake	Abid <i>et al.</i> (2017), Mohsin <i>et al.</i> (2017)
<i>Aspergillus niger</i>	<i>phyA</i>	Arabidopsis	Improved phosphorus acquisition from soil	Mudge <i>et al.</i> (2003)
	<i>phyA</i>	<i>Brassica napus</i>	Improved phosphorus acquisition from soil & alternative to commercial phytase	Wang <i>et al.</i> (2013)
	<i>phyA, phy2A</i>	Maize	Phosphorus availability increased	Drakakaki <i>et al.</i> (2005), Chen <i>et al.</i> (2008)
	<i>phyl</i>	Rice	Enhanced inorganic phosphates	Liu <i>et al.</i> (2006)
	<i>phyA</i>	Sesame	Improved phosphorus acquisition	Jin <i>et al.</i> (2004)
	<i>phyA</i>	Soybean	Alternative to commercial phytase	Li <i>et al.</i> (1997)
	<i>phy, phyA</i>	Tobacco	Improved phosphorus acquisition from soil, improved broiler growth, proved to be an alternative to commercial phytase	Pen <i>et al.</i> (1993), Verwoerd <i>et al.</i> (1995), George <i>et al.</i> (2005, 2009), Giles <i>et al.</i> (2018)
	<i>phyA</i>	Wheat	Phytate degraded to lower forms	Brinch-Pedersen <i>et al.</i> (2000), Geetha <i>et al.</i> (2019)
	<i>phyA</i>	Tobacco	Improved phosphorus acquisition from soil	George <i>et al.</i> (2009)
	<i>phy</i>	Rice	Increased shelf-stability	Hamada <i>et al.</i> (2005)

Applications in Aquaculture and Fish Farming

Feed costs constitute up to 70% of the total fish production costs in aquaculture (Rumsey, 1993). The anti-nutritional effect of phytates is more problematic in fish due to their short gastrointestinal tracts (Richardson *et al.*, 1985), which in turn hinders the use of plant-derived protein in fish feed. Phytase is thus useful as a means to promote the use of low-cost plant meals in the aquaculture industry and to maintain the acceptable phosphorus levels in water. The use of phytases in fish feed has increased during the past a few decades, mainly in response to concerns over aquatic phosphorus pollution (Cao *et al.*, 2007). It is well documented that the use of microbial phytase in fish feed can enhance the bio-availability of phytate-bound phosphorus and nitrogen, and thus less phosphorus is discharged into the aquatic environment (Rodehutsord and Pfeffer, 1995).

The effect of commercial phytase (Natuphos) from *A. niger* on common carp (*Cyprinus carpio*) was investigated by Schafer *et al.* (1995), which resulted in improved utilization of phytate phosphorus, reduced phosphorus secretion as well as enhanced body weight and body phosphorus content. Transgenic Japanese medakas (*O. latipes*) producing *A. niger* phytase were created to examine the feasibility and efficacy of producing fish capable of degrading phytate (Hostetler *et al.*, 2005). Most of the reports on phytase application in aquaculture are using the commercially available fungal phytases. However, yeast and fungal phytases provide the added advantage in fresh water and marine aquaculture due to their probiotic role. When plant based low phosphorus diets for Nile tilapia (*Oreochromis niloticus*) were supplemented at 750 U kg⁻¹ with an engineered phytase SP1002, having improved properties such as an elevated pH optimum, increased stability against proteolytic activity and heat, produced by a genetically modified strain of *Hansenula polymorpha*, significantly improved digestibility of protein, calcium and phosphorus was observed (Liebert and Portz, 2007). The cell-bound phytase of *P. anomala* was also found to be a useful supplement to plant-based feed for marine as well as freshwater fish (Vohra *et al.*, 2011). During fish feeding trials on juvenile milkfish *Chanos chanos*, soybean meal was supplemented with the cell-bound phytase and used to replace fishmeal. This resulted in positive effects on growth of the fish, suggesting the use of *P. anomala* phytase in environment-friendly mass culturing of milkfish (Hassan *et al.*, 2009).

Phytases in Plant Growth Promotion and Soil Amendment

Around 10%–50% of the total organic phosphorus content in the soil is present as phytic acid (Mullen, 2005). This is not readily available to plants because it complexes with cations or adsorbs to various soil components. Hence, there is a need to mobilize this phosphorus source (Richardson *et al.*, 2001). The presence of plant growth-promoting fungi in the plant rhizosphere improves the availability by solubilizing/mineralizing phosphorus (Zhang *et al.*, 2016; Hossain *et al.*, 2017; Singh and Satyanarayana, 2010). Several extracellular phytase producing fungi like *A. flavus*, *A. fumigatus* and *A. rugulosus* that inhabit the rhizosphere have been investigated for

their role in promoting plant growth by improving phosphorus nutrition (Tarafdar and Rao, 1996). Also, species of *Trichoderma* and *Penicillium* have been reported to increase the extractable organic phosphorus in alkaline soils (Gaiind and Nain, 2015). These studies clearly indicated that fungal phytase supplementation to soils lead to enhanced plant growth and productivity levels.

Another approach to improve the utilization of phytate phosphorus in soils is to generate transgenic plants expressing phytase. This would help in reducing dependency on phosphorus fertilizers in agriculture. Such transgenic plants secrete extracellular phytases into the rhizosphere that leads to an increased level of phosphorus availability for plants. Both fungal and bacterial phytase genes have been used to develop transgenic plants. The *A. niger* NRRL 3135 *phyA* gene was expressed in *Arabidopsis* aiming to secretion of the transgenic phytase into the rhizosphere. This resulted in a transgenic *Arabidopsis* line with improved phosphorus nutrition and growth compared to the control (Richardson *et al.*, 2001). Transgenic *Brassica napus* that expressed either the *A. niger phyA* or *appA* gene were created, which showed improved biomass yield in the presence of phytates as the only source of phosphorus (Wang *et al.*, 2013). Experiments aimed at obtaining plants with enhanced phytase activity have also been carried out with mustard, tobacco, soya, wheat, sweet potato, and canola (Balaban *et al.*, 2017). Certain properties of phytase are important in determining phytate hydrolysis such as its isoelectric point (pI) (George *et al.*, 2007; Lei *et al.*, 2013). A phytase of *Peniophora lycii* is more effective in hydrolyzing phytate than *A. niger* phytase, as the former has a lower pI (3.6) compared to the latter (5.0), thus allowing the *P. lycii* phytase to remain more soluble in the soil environment. Phytases with a low pI are more effective in hydrolyzing phytates in acidic soil, and in basic soil, phytases with high pI values are preferable. Thus, phytase genes sourced from various fungi have been used to create transgenics of tobacco, soybean, wheat and several other plants (Table 1), which further helps in mitigating the need for phosphorus fertilizers in agriculture as the release of such extracellular phytases from the roots of transgenic plants lead to an increased level of phosphorus and minerals available for plants, thereby improving overall plant growth and creating favorable conditions for neighboring plants (Reddy *et al.*, 2013).

Utility of Phytases in Environmental Pollution Mitigation

Phosphorus is an essential nutrient for living systems, however, too low or too high levels of this nutrient can cause problems. As discussed earlier, phytase supplementation in animal feeds is meant to overcome the problem of underutilization of phytates and the cost of Pi addition. The unutilized phytate phosphorus tends to accumulate in the environment as fecal matter (Mullaney *et al.*, 2000). This unutilized phytate is degraded by the phytases produced by soil and water-borne microbes, due to which the excess Pi runs off into water bodies that causes eutrophication and algal growth (Vohra and Satyanarayana, 2003; Kaur *et al.*, 2007). The pre-treatment of animal feeds with phytase has benefits of increasing availability of Pi, helping in nutrition and at the same time mitigating the problem of phosphorus pollution of aquatic environments. Lei *et al.* (1993) showed that the addition of PhyA from *A. niger* to a corn-soybean based feed with low phosphorus content enabled weanling pigs to utilize dietary phytate, whereby the retention of dietary phosphorus by pigs was increased by 50% and the simultaneous fecal excretion of phosphorus was lowered by 42%. The supplementation of feed of broiler chicks with cell-bound phytase of *P. anomala* not only resulted in improved growth and better phosphorus retention in the body, but there was also reduced excretion of phosphorus in the feces (Vohra *et al.*, 2006). This cell-bound phytase was also found to be a useful supplement to plant-based feed for environment-friendly cultivation of marine (*Chanos chanos*) and freshwater (*Labeo rohita*, *Clarias batrachus*) fish with diminishing excretion of phosphorus in the water bodies (Hassan *et al.*, 2009; Vohra *et al.*, 2011). Phytases were first introduced as animal feed supplements for environmental reasons, but soon their other nutritional and health benefits were realized.

Use of Phytases in Generating Specific Inositol Phosphates With Therapeutic Applications

There is an ever-increasing interest in inositol phosphates due to their role in transmembrane signaling and mobilization of calcium from intracellular reserves (Billington, 1993). The inositol phosphate derivatives find use as enzyme stabilizers (Siren, 1986a), enzyme substrates for various metabolic studies, inhibitors of enzymes and thus, as potential drugs, and as chiral building blocks (Laumen and Ghisalba, 1994). Certain *myo*-inositol phosphates also have beneficial health effects. The physiological functions are dependent on the number and position of the phosphate groups on the *myo*-inositol ring. The use of specific inositol triphosphates as pain killers has also been proposed (Siren, 1995). The esters of inositol triphosphate have been shown to exert significant inhibitory effects on retroviral infections including HIV (Siren, 1998). Certain *myo*-inositol phosphates have been suggested to have specific beneficial health effects such as reducing the risk of heart disease (Potter, 1995), renal stone formation (Modlin, 1980) and certain cancers (Graf and Eaton, 1993; Shamsuddin and Vucenik, 1999).

The sequential hydrolysis of *myo*-inositol hexakisphosphate by phytases releases various lower inositol phosphates, which are useful for studying their physiological effects. An efficient bioreactor with immobilized phytase could be advantageous for producing various lower isomers of phytate. Quan *et al.* (2003) immobilized cells of phytase producing *Candida krusei* in Ca-alginate gel beads for the preparation of various inositol phosphates, and the pure isomers were then isolated by ion-exchange chromatography.

Phytases can also be used to prepare novel specific phytate derivatives (Greiner and Konietzny, 1996). The phytase from *S. cerevisiae* was used for generating *D*-*myo*-inositol 1,2,6-triphosphate, *D*-*myo*-inositol 1,2,5-triphosphate, *L*-*myo*-inositol 1,3,4-triphosphate and *myo*-inositol 1,2,3-triphosphate (Siren, 1986b). Chemical synthesis of these compounds is difficult, requiring protection and deprotection steps (Billington, 1993). Thus phytases, which convert phytic acid to specific lower *myo*-inositol phosphates, would be useful for industrial production of the specific *myo*-inositol phosphate derivatives. Among the advantages of enzymatic hydrolysis over chemical synthesis are the stereospecificity and mild reaction conditions.

Table 2 Some examples of commercial fungal phytases

Organism of origin	Commercial name of the product	Company
<i>Aspergillus awamori</i>	Avizyme®	Finnfeeds International
<i>Aspergillus niger</i>	Natuphos®	BASF
	Allzyme®	Alltech
	Finase® P/L	AB Vista
<i>Penicillium funiculosum</i>	Rovabio®	Adisseo
<i>Peniophora lycii</i>	Ronozyme® P	Novozymes/DSM

Virtual Peroxidases Derived From Phytases and Their Uses

Peroxidases are enzymes that catalyze a wide variety of oxidations with hydrogen peroxide being the main oxidant. Considering the structural similarity of the active site of vanadium-dependent haloperoxidases, fungal phytases and acid phosphatases, a semisynthetic peroxidase was designed (Van de Velde *et al.*, 2000). In this enzyme, vanadate ion was incorporated into the active site of *A. niger* (*ficuum*) NRRL 3135 phytase, which resulted in the transformation of native phosphohydrolase activity of phytase into virtual peroxidase, which could catalyze enantio-selective oxidation of prochiral sulfides. It was observed that only histidine acid phosphatases with the active site sequence 'RHGXRRP' could function as a peroxidase when vanadate ion was incorporated into the active site. Vanadate serves as a phosphate analog and can inhibit the phytate hydrolyzing activity of phytase, thus making the enzyme behave like a vanadate-dependent haloperoxidase (Ullah *et al.*, 2011). The recombinant phytases of *P. anomala* and *S. thermophile* were also demonstrated to display haloperoxidase activity after insertion of vanadate into their active sites (Joshi and Satyanarayana, 2015b; Ranjan and Satyanarayana, 2016). The vanadate haloperoxidases have multifarious applications like in immunoassays, diagnostics, and as anti-microbial agents.

Other Applications

A novel application of phytases is in different biosensors. As phytic acid plays an important environmental role in poultry industry and has a health aspect in food industry, a phytase-based biosensor was developed for simple, one step quantitative detection of phytic acid based on the sequentially acting enzymes, *i.e.*, phytase and pyruvate oxidase. This was the first report of the use of phytase in biosensors (Mak *et al.*, 2004). Thereafter, a yeast cell (*Arxula adeniniivorans*) based assay using phytase was developed for the detection of estrogenic activity in wastewater (Hahn *et al.*, 2006). The photometric assay enabled estrogen determination in sewage samples within 30 h. Another innovation was the use of the yeast *Candida melibiosica* strain 2491 producing a high phytase, as a biocatalyst in microbial fuel cell, by which the assimilation of inorganic phosphates was coupled with the electrochemical process (Hubenova and Mitov, 2010). Organophosphorus pesticides are chemically phosphoric acid esters which act on pests by inhibiting acetylcholine esterase activity. These compounds are not easy to eliminate from the environment, therefore leading to their bioaccumulation. Recently, phytase from *A. niger* NCIM 563 was discovered that actively degrades organophosphorus pesticides like chlorpyrifos, monocrotophos and methyl parathion (Shah *et al.*, 2017). This field can be explored further for its potential in the management as well as control of environmental phosphorus pollution. Ionic liquid mediated self-assembled phytase nanospheres were shown to have anti-tumor properties that could be enhanced in efficiency by adding platinum ions on their surface and loading them inside the anti-tumor drug curcumin that is present in turmeric, an Indian spice (Soni *et al.*, 2015). These nanospheres containing phytase I from *A. niger* are promising in therapeutics for development of multifunctional drug-delivery systems as they exhibit 25% anti-cancer effect that improved to 90% in platinum-phytase-curcumin nanospheres. The platinum-phytase spheres are also amenable as an efficient green and reusable phytate degradation system.

Commercially Available Phytases

Phytases are playing a significant role in the feed and food industry. In 2015, phytase had a highest revenue share of 83.6% of the food and feed industry (See Relevant Website Section) and accounted for annual sale of US\$ 350 million. The first commercialized phytase called Natuphos was derived from *A. niger* and launched by BASF (Ludwigshafen, Germany) in 1991 (Haefner *et al.* 2005; Ariza *et al.* 2013). This was followed by the commercial product Ronozyme® P, a 6-phytase from *Peniophora lycii*. For producing phytase on a commercial scale, fungal hosts are preferred, because they can produce high enzyme titers and introduce post-translational modifications like N-linked glycosylation (Guo *et al.*, 2008; Greiner and Konietzny, 2012) that can result in improved thermostability (Wu *et al.*, 2014), a property desirable for phytase. Examples of phytases used in industrial scale and some of their commercial products are listed in Table 2.

Conclusions

Several fungal phytases seem to be suitable for various biotechnological applications due to their broad substrate spectrum along with thermostability, acid-stability and versatility in terms of applicability (conventional as well as novel).

Phytases enable enzymatic green phosphate generation and they are especially useful in animal nutrition, due to the increasing concerns about problems related to phosphorus pollution in regions of intense animal farming. However, their potential applications in various other industries including human nutrition, soil fertility, management of environmental phosphorus pollution as well as novel uses in other fields, makes them enzymes with high overall value. In addition, many phytase producing filamentous fungi and yeasts are GRAS organisms or have probiotic potential, making them safe for use. Also bioengineering is enabling the use of phytases by generating phytate hydrolyzing transgenic plants and animals. Simultaneously, the discovery of new fungal phytases with higher production levels and desirable characteristics for specific applications is required.

Modification of Plant Carbohydrates Using Fungal Enzymes

Mirjam A Kabel, Matthias Frommhagen, Peicheng Sun, and Henk A Schols, Wageningen University and Research, Wageningen, The Netherlands

© 2021 Elsevier Inc. All rights reserved.

Introduction

A main driver of terrestrial carbon-recycling is the continuous decay of (dead) plant biomass, mainly mediated by the combined activities of highly dynamic fungal communities (Lladó *et al.*, 2017; López-Mondéjar *et al.*, 2018; Ontl and Schulte, 2012). Even related fungi from similar habitats have been shown to produce complementary enzyme-sets acting on the same substrate, which points to an evolutionary selection of efficient communities (Benoit-Gelber *et al.*, 2017; Benoit *et al.*, 2015; Hu *et al.*, 2011). Fungal enzymes are also major biocatalysts in many food and biotechnology applications, and essential for the transition from conventional chemical processes to biorefineries (Dilokpimol *et al.*, 2018; Frommhagen *et al.*, 2018; Himmel *et al.*, 2007; Straathof, 2014). Nevertheless, selection of the right fungal strain and most optimal enzymes for specific applications remains challenging and will be discussed in detail in this chapter.

Plant biomass is largely composed of cell wall material mostly originating from primary and secondary cell wall layers (Carpita, 2000). In general, polysaccharides are the most abundant cell wall components, next to structural proteins and aromatic lignin (Pauly and Keegstra, 2008). The primary cell wall surrounds the cell and is the major part of the plant cell wall in fruits and vegetables. This layer is mainly composed of cellulose microfibrils embedded in a network of pectin and various hemicelluloses, i.e., xyloglucan, xylan or mannan (Cosgrove, 2005). Exact compositions vary for example per source, tissue type or environmental growing conditions. The secondary plant cell wall is deposited on the outside of the plasma membrane surrounding the cell lumen, and on the inside of the primary cell wall. This secondary cell wall represents the main part of the dry matter of lignocellulosic feedstocks. Examples of the latter are grass-like agricultural by-products or hard- and softwoods.

It should be noted that the ratio of primary versus secondary cell wall components differs for example per botanical source and tissue type, and that certain types of biomass (i.e., sugar beet pulp, rape seed meal) do not fit in a strict system defining only “primary cell wall rich fruits and vegetables” versus “secondary cell wall rich grasses and woods”.

The secondary cell wall contains cellulose and hemicellulose, in addition to the heterogenous aromatic polymer lignin (Boerjan *et al.*, 2003; Cosgrove, 2005; Meents *et al.*, 2018; Pauly and Keegstra, 2008). Hemicellulose is mainly represented by (acetylated) xylan in grasses and hardwoods or mannan in softwoods (Ebringerová *et al.*, 2005; Gírio *et al.*, 2010; Scheller and Ulvskov, 2010).

This chapter aims to give an overview of the structures of most occurring plant cell wall polysaccharides and corresponding fungal plant cell wall modifying enzymes with a focus on plant cell wall degradation.

Carbohydrate Active Enzyme Classification

Since the early search for enzymes, to benefit products and usually greener processes for the food or biorefinery industry, carbohydrate active enzymes have received elaborate attention (Frommhagen *et al.*, 2018; Gírio *et al.*, 2010; Himmel *et al.*, 2007; Jonathan *et al.*, 2017; Pauly and Keegstra, 2008). As more and more enzymes were discovered, varying in their origin, substrate specificity and mode-of-action, soon the need for a classification to improve selection and optimization of enzymes became evident. With the increasing amounts and easiness to obtain genome-based information many enzymes could be recognized based on gene level. Although this gene information does not provide data on actual enzyme functions, in 1998 it provided the basis for classification with the foundation of the so-called Carbohydrate-Active enZymes database (see “Relevant Websites section”; Lombard *et al.*, 2014). The CAZy database describes families of structurally-related catalytic and carbohydrate-binding modules (or functional domains) of enzymes that degrade, modify, or create glycosidic bonds. Currently, five enzyme classes are defined in CAZy, each containing multiple families: Glycoside Hydrolases (GHs), Glycosyl Transferases (GTs), Polysaccharide Lyases (PLs), Carbohydrate Esterases (CEs) and Auxiliary Activities (AAs). Within the amino acid sequence similarity-based classification, families represent mutual biochemical mechanisms and protein structure information rather than actual substrate specificity. The latest developments comprise establishment of subfamilies, which are expected to better represent substrate specificity (Dilokpimol *et al.*, 2018).

GHs are by far the largest CAZy class and GH-candidates are widespread throughout the fungal kingdom (see “Relevant Websites section”; Lombard *et al.*, 2014). Additionally, many food, biomedical and biorefinery applications built on the use of various GHs, and, therefore, this class comprises the most biochemically and structurally characterized enzymes. GHs are considered to mainly follow either inverting or retaining mechanisms (Davies and Henrissat, 1995; McCarter and Withers, 1994). A distinct difference for retaining over inverting enzymes is the formation of a glycosyl enzyme intermediate, and, consequently, a second reaction step (Davies and Henrissat, 1995; McCarter and Withers, 1994). In the case that in this second step, instead of water leading to hydrolysis, another carbohydrate molecule acts as acceptor, transglycosylation takes place (Bissaro *et al.*, 2015). Obviously, at high carbohydrate concentrations, the equilibrium will be directed towards transglycosylation with minor hydrolysis

Fig. 1 Amylose (I), amylopectin (II) and inulin (III) structures and corresponding fungal hydrolytic enzymes. In green enzymes active towards the backbone of the polysaccharide are indicated, while in black exo-active and substitution removing enzymes are shown.

taking place. In contrast, GTs use “activated” sugar phosphates as glycosyl donor and, therefore, are out of the scope of this chapter (Lairson *et al.*, 2008).

PLs are distinct from GHs as PLs specifically cleave uronic acid-containing polysaccharides, while they act via a β -elimination mechanism resulting in unsaturated (oligomeric) products, having a double bond in the non-reducing end residue, and in a new reducing end (Benen and Visser, 2003; Lombard *et al.*, 2014).

CEs catalyze the de-O- or de-N-acylation of substituted carbohydrates (Biely, 2012; Nakamura *et al.*, 2017). Two classes of substrates for carbohydrate esterases are to be considered: those in which the sugar plays the role of the “acid”, such as pectin methyl esters and those in which the sugar behaves as the alcohol, such as in acetylated xylan (Benen *et al.*, 2003; Benen and Visser, 2003; Nakamura *et al.*, 2017). The most common CE reaction mechanism is the Ser-His-Asp catalytic triad catalyzed deacetylation, also found in classical lipases and serine proteases (Benen *et al.*, 2003; Rauwerdink and Kazlauskas, 2015).

Catalytic proteins listed in AA families are redox enzymes, which are assumed to work together with other CAZymes. These AA families have been introduced after the discovery of the lytic polysaccharide monooxygenases (LPMOs) around 2010 (Lombard *et al.*, 2014), and classification and characterization of these AA members is still in its infancy.

Fungal Plant Carbohydrate Degrading Enzymes and Their Substrates

Two main plant storage polysaccharides are starch and inulin and their enzymatic degradation, which is relatively well understood, is highly relevant for many food and agro-industrial processes. In contrast, understanding the wide variety of plant cell wall polysaccharide structures and fungal enzymes to degrade these structures remains a major challenge. Therefore, this chapter shortly reviews starch and inulin and their enzymatic degradation, while the main part of this chapter will review plant cell wall polysaccharide structures and the fungal enzymes needed to degrade them.

Starch and Inulin Degrading Glycoside Hydrolases

As just mentioned, starch and inulin are considered natural storage carbohydrates, which form an energy reserve for plants. Many grains (i.e., corn, wheat) and tubers (i.e., potato) contain about 60%–80% of starch on a dry matter (DM) basis (Bach Knudsen, 1997). Relatively high amounts of inulin can be found in various roots, in particular chicory roots (10%–15% of DM) (Schaafsma and Slavin, 2014).

Starch is composed of two homoglycans, amylose and amylopectin (van der Maarel *et al.*, 2002). Amylose is a linear polysaccharide composed of α -(1 $\rightarrow$ 4)-linked glucosyl residues, while amylopectin has additional α -(1 $\rightarrow$ 6)-branching points (Fig. 1). Fungal starch degrading GHs comprise α -amylases in GH13 (Saranraj and Stella, 2013), debranching amylo-(α -1,6)-glucosidases in GH133, amyloglucosidases in GH15 and some α -glucosidases in GH31 (Fig. 1; Table 1). The large GH13 family is further

Table 1 Selected glycoside hydrolase (GH) families, and lytic polysaccharide monooxygenases (LPMOs) in auxiliary activity (AA) families taking part in starch, inulin, pectin, cellulose and hemicellulose degradation^a. Only CAZy families with over five relevant fungal members are indicated

Major substrate	Enzyme	CAZy (sub-)family ^a
Starch	α -Amylases	GH13_1, GH13_5, GH13_32
	Amylo-(α – 1,6)-glucosidases	GH133

^aBased on CAZy (CAZy.org; Lombard *et al.*, 2014).

divided in over 40 subfamilies, and while originally fungal α -amylases were mostly classified in subfamily GH13_1, recent work showed their presence in subfamilies GH13_5 and GH13_32 as well (Stam *et al.*, 2006; Janíčková and Janeček, 2020). Debranching pullulanases have been suggested to classify in GH13_12–14, GH13_39 and GH13_41, thoroughly reviewed by Møller *et al.* (2016), but so far no fungal candidates have been suggested (Xu *et al.*, 2013). In fungi, the amylo-(α -1,6)-glucosidases from GH133 might be important for debranching purposes.

Candidates from all three fungal starch degrading GH families are wide-spread, and are for example found in *Aspergillus niger*, *Aspergillus oryzae*, *Podospora anserina* and *Rhizopus oryzae* (van den Brink and de Vries, 2011). The α -amylases are known to endo-act, meaning that they can cleave the glycosidic linkages inside the α -(1 $\rightarrow$ 4)-linked glucan backbone resulting in dextrans of various degree of polymerization (DP). In general, α -amylases cannot degrade the backbone in the vicinity of an α -(1 $\rightarrow$ 6)-branching

Fig. 2 Cellulose (I), cellobiose and cellotriose as example of cello-oligosaccharides (II) with corresponding fungal hydrolytic and oxidative enzymes. In green enzymes active towards the backbone of the polysaccharide are indicated, while in black exo-active and substitution removing enzymes are shown. For the detailed mechanism of lytic polysaccharide monooxygenase (LPMO) see Fig. 6.

point. Amyloglucosidases and α -glucosidases release one glucosyl residue per cleavage from the chains ends, a process that is known as exo-active (Jonathan *et al.*, 2015; Warren *et al.*, 2015). Amyloglucosidases can also act towards the α -(1 $\rightarrow$ 6)-linked branching points, albeit at a slower rate compared to cleavage of the α -(1 $\rightarrow$ 4)-linkages (Jonathan *et al.*, 2016). Most characterized fungal amyloglucosidases act from the non-reducing end (Jonathan *et al.*, 2016; Karim and Tasnim, 2018).

The name inulin is used for a group of heterogenous polysaccharides, built from a terminal glucosyl residue coupled to (1 $\rightarrow$ 2)-linked fructosyl residues ranging in DP from 2 to > 100 (Fig. 1; Schaafsma and Slavin, 2014). Inulin can be hydrolyzed by either acid hydrolysis or endo-inulinases into smaller oligomers. Inulin molecules with a DP lower than 10 are also considered as fructo-oligosaccharides. Both inulin and fructo-oligosaccharides are not digestible by the human digestive enzymes and, therefore, considered as dietary fiber (Raninen *et al.*, 2011). Fungal inulin degrading enzymes are mostly found in the GH32 family, for example (exo-)inulinases (Table 1). Fungi vary considerably in abundance of GH32 enzymes, for example multiple GH32 inulinase encoding genes are present in the genome of various *Aspergillus* strains, while these are absent in other fungi, such as *Trichoderma reesei* and *Phanerochaete chrysosporium* (van den Brink and de Vries, 2011). GH32 enzymes are retaining enzymes, which for some of the (putative) fungal GH32 members might result in transglycosylation activity forming fructan-polysaccharide mixtures (Lasseur *et al.*, 2009).

Cellulose Degrading Glycoside Hydrolases

Cellulose is the main polysaccharide in plant cell walls of all photosynthetic higher plants and algae. The structure is a homogeneous linear polymer of β -(1 $\rightarrow$ 4)-linked glucan chains, which form microfibrils via hydrogen bonds and van der Waals forces (Jarvis, 2003). Alternate (rotated by 180°) glucosyl units are linked to form a flat ribbon (Fig. 2) tightened by hydrogen bonds (Jarvis, 2003). Dependent on the source, cellulose varies in crystalline forms and the microfibrils differ in length, i.e., a very high DP (14,000 – 15,000), in for example the secondary cell wall of cotton, or a shorter DP (between 500 and 8000) in primary cell walls (Atalla and Vanderhart, 1984; Mohnen *et al.*, 2008). Crystalline regions alternate with amorphous regions as a result of a variability on hydrogen bonding or interaction with other polymers, such as hemicelluloses or lignin (Atalla and Vanderhart, 1984).

The degradation of cellulose is catalyzed by the action of three different classes of cellulases: endoglucanases (endo- β -1,4-glucanases), exo-active cellobiohydrolases (CBHs) and β -1,4-glucosidases (BGLs) (Bischof *et al.*, 2016; Lynd *et al.*, 2002; Reese, 1956). The latter hydrolyze soluble cello-oligosaccharides into glucose, acting from the non-reducing ends, and are predominantly found in the GH1 and GH3 families (Table 1; Lynd *et al.*, 2002). Endoglucanases degrade internal β -(1 $\rightarrow$ 4)-linked glucan bonds in cellulose, and fungal candidates are distributed over the GH families 5, 7, 12 and 45. Cellobiohydrolases cleave off cellobiose (DP2) from β -(1 $\rightarrow$ 4)-linked glucan chain from either the reducing (CBHI) or non-reducing (CBHII) ends and fungal candidates are found in the GH7 and GH6 families, respectively (Lynd *et al.*, 2002). CBHs are considered to be important for the hydrolysis of, in particular, crystalline parts of cellulose (Teeri, 1997), while endo-glucanases prefer acting towards amorphous regions (Béguin and Aubert, 1994). Notably, the classification of cellulose degrading enzymes into these categories is oversimplified since endoglucanases have already been shown to cleave cellulose randomly or processively and CBHs also vary in their mode-of-action from strictly exo-acting to highly processive (Payne *et al.*, 2011). That might also be the reason that fungi usually possess multiple

Fig. 3 Xyloglucan and corresponding fungal hydrolytic and oxidative enzymes. In green enzymes active towards the backbone of the polysaccharide are indicated, while in black exo-active and substitution removing enzymes are shown. For the detailed mechanism of lytic polysaccharide monooxygenase (LPMO) see Fig. 6. Letters (in red) in the structure indicate letter-code nomenclature for the (decorated) glucosyl units according to Fry *et al.* Reproduced from Fry, S.C., York, W.S., Albersheim, P., *et al.*, 1993. An unambiguous nomenclature for xyloglucan-derived oligosaccharides. *Physiologia Plantarum* 89, 1–3.

endoglucanase, CBH and BGL candidates (van den Brink and de Vries, 2011). For example, *Aspergillus niger* has five endoglucanase (GH5 and 12), four CBH (GH6 and 7), and 13 BGL (GH1 and 3) candidates, while *Myceliophthora thermophila* C1 comprises in total over 50 cellulose degrading enzymes (van den Brink and de Vries, 2011; Verdoes *et al.*, 2007).

It has been shown that CBHs are inhibited by their product cellobiose, which obviously hinders complete saccharification of cellulose (Bischof *et al.*, 2016). Therefore, cellulase mixtures are often supplemented with BGLs. Most commercial cellulase cocktails are enriched in the powerful *T. reesei* cellulases. Notably, these mixtures are often supplemented with BGLs from other fungi, i.e., like various *Aspergilli* species, as the BGLs of *T. reesei* are mostly membrane bound and, hence, not excreted by the fungus (Sørensen *et al.*, 2013). Another bottleneck for efficient cellulose degradation is the glucose inhibition of BGLs, hence, candidates able to maintain high conversion at high glucose concentration are aimed at (Sørensen *et al.*, 2013).

Other enzyme or protein classes that are involved in the degradation of cellulose are, for example, expansins, swollenins and lytic polysaccharide monooxygenases (LPMOs). These proteins are less studied and summarized as non-hydrolytic cellulose active proteins (NHCAPs) (Ekwe *et al.*, 2013). In particular, LPMOs possess a different catalytic mechanism compared to classical cellulose hydrolases, which is explained in detail later in this chapter.

Xyloglucan Degrading Glycoside Hydrolases

Xyloglucans are mostly found in the primary cell walls of higher plants (Ebringerová *et al.*, 2005; Gírio *et al.*, 2010; Hayashi, 1989; Vincken *et al.*, 1997). Contents based on dry matter vary, for example, the primary cell wall of poplar is composed of up to 6% (w/w) of xyloglucan (Park *et al.*, 2004), while those of *Arabidopsis thaliana* comprise between 20% and 25% (w/w) of xyloglucan (Ebringerová *et al.*, 2005). Xyloglucan consists of a backbone of β -(1 $\rightarrow$ 4)-linked glucosyl residues being α -(1 $\rightarrow$ 6)-substituted with xylosyl residues. For the majority of xyloglucan structures, the xylosyl substituents can be further extended with galactosyl and fucosyl residues (Fig. 3), while further substitution with arabinosyl residues is particularly found for solanaceous xyloglucans. The (substituted) glucosyl backbone units of xyloglucans occur in a repetitive pattern, which are indicated with a one-letter coding system code (G, X, L, ...) for an eased identification and characterization (Fig. 3; Fry *et al.*, 1993).

The backbone of xyloglucan is cleaved by endo- β -1,4-glucanases, which are present in the GH5, 12, 16 and 74 families (Kubicek *et al.*, 2014). These enzymes are widespread in the fungal kingdom, and usually plant cell wall degrading fungi possess multiple candidate genes for xyloglucan degradation in their genome (Kubicek *et al.*, 2014; van den Brink and de Vries, 2011). In particular, xyloglucan active endo- β -1,4-glucanases of family GH74 have recently been shown to be further dividable into five subgroups via structure based phylogenetic analysis (Arnal *et al.*, 2019). Although in GH74 mainly bacterial candidates are found (see “Relevant Websites section”; Lombard *et al.*, 2014), fungal members seem to co-cluster (Arnal *et al.*, 2019). The subgroups coincide with a difference in mode-of-action and regio-specificity: a major subgroup hydrolyzed the xyloglucan backbone non-specifically at G or X (i.e., non-processive), while another subgroup seem to correlate to a more processive xyloglucan degradation (Arnal *et al.*, 2019; Vincken *et al.*, 1997). Note that only few endo- β -1,4-glucanases are characterized to date as xyloglucan specific enzymes, not showing activity towards other substrates such as β -glucan or cellulose (Pauly *et al.*, 1999; Vincken *et al.*, 1997). Further, β -glucosidases (GH1 and GH3), if not hindered by the xyloglucan substitution, can cleave off (non-substituted) glucose of xylogluco-oligosaccharides, like for cellodextrins (Fig. 2). Such β -glucosidases have more freedom to act after activity of or in synergy with various xyloglucan side chains removing enzymes, such as α -xylosidases (GH31), α -galactosidases (GH27 and GH36) and α -fucosidases (GH95) (Table 1; de Vries and Visser, 2001; Hayashi, 1989).

Fig. 4 The main pectic structures: substituted rhamnogalacturonan I (RG-I; I) and homogalacturonan (HG; II), including corresponding fungal hydrolytic enzymes and lyases. In green enzymes active towards the backbone of the polysaccharide are indicated, while in black exo-active and substitution removing enzymes are shown. Ferulic acid esters have been shown to occur on the pectic arabinan and galactan side-chains, but their generic character has yet to be defined. Therefore, ferulic acid esters and ferulic acid esterases are not depicted in the figure.

Like for cellulose, activity of non-hydrolytic LPMOs towards xyloglucan has been shown resulting in chain-cleavage, which is further discussed below.

Pectin Degrading Glycoside Hydrolases and Polysaccharide Lyases

Pectin mostly occurs in plant primary cell walls and comprises a variety of polysaccharide structures. Predominant pectic structures are homogalacturonan (HG) and substituted rhamnogalacturonan I (RG-I) with a lower abundance of heavily substituted rhamnogalacturonan II (RG-II) (Fig. 4; Ralet *et al.*, 2009; Voragen *et al.*, 2009; Wong, 2008). HG has a backbone of α -(1 $\rightarrow$ 4)-linked galacturonic acid residues, which can be esterified at the carboxyl group at C6 with methanol. HGs from specific sources, such as from potato or sugar beet, have been shown to be esterified at O2 and/or O3 of the galacturonic acid with acetic acid (Ralet *et al.*, 2009; Voragen *et al.*, 2009). In plants, pectin is highly methyl esterified, which decreases during ripening due to endogenous methyl esterase activity. In the RG-I backbone, rhamnosyl (Rha) residues alternate with galacturonic acid (GalA) via [1 $\rightarrow$ 4]- α -GalA-(1 $\rightarrow$ 2)- α -Rha-(1 $\rightarrow$) linkages. Largely depending on the source, 20%–80% of the Rha residues in RG-I are (1 $\rightarrow$ 4)-substituted and the length of the side-chains vary from DP1 to >40 (Ralet *et al.*, 2009; Voragen *et al.*, 2009; Wong, 2008). Side chains consist mainly of arabinans or β -(1 $\rightarrow$ 4)-linked (type I) (arabino-)galactans (Fig. 4). Arabinans are built from a chain of α -(1 $\rightarrow$ 5)-linked arabinosyl residues, which can be further substituted at the O2 or O3 with arabinosyl residues. Arabinogalactans constitute a β -(1 $\rightarrow$ 4)-linked galactosyl backbone, which is further ramified at the O3 and/or O6 with variable levels of arabinosyl and/or galactosyl residues (Ralet *et al.*, 2009; Voragen *et al.*, 2009; Wong, 2008). Next to HG and RG-I, pectin can be composed of RG-II and xylogalacturonan (XGA). Rhamnogalacturonan II (RG-II) is a structurally very complex element, composed of a GalA-backbone and substituted with rare sugars such as 2-O-methylxylosyl, 2-O-methylfucosyl and aceric acid (= 3-C-carboxy-5-deoxy-L-xylofuranose) residues (O'Neill *et al.*, 2004). RG-II is present in all plants and its levels are typically low. In XGA, GalA residues are substituted with, β -(1 $\rightarrow$ 3)-xylosyl residues (O'Neill *et al.*, 2004). The presence of XGA does not seem to be universal, but has been reported for many reproductive tissues of apple, watermelon, onion, potato and pear (Voragen *et al.*, 2009).

Fungal enzymatic HG and RG-I degradation relies on activities from both GH and PL families (Fig. 4), while enzymes playing a significant role for degradation of the complex RG-II structure are, so far, not well defined. Fungal HG and RG-I backbone degrading hydrolases are mostly found in GH28 as either polygalacturonases (PGs) for HG or rhamnogalacturonan hydrolases (RGHs) for RG-I. For a complete degradation of the pectin backbone, also exo-acting enzymes like exo-PGs, RG-rhamnohydrolases (GH78) and RG-galacturonohydrolases (GH138) are required (Gilbert *et al.*, 2008). As the backbone degrading endo- and exo-acting hydrolases are largely hindered by backbone substitutions, accessory enzymes are essential for complete degradation.

Fig. 5 Xylan and corresponding fungal hydrolytic enzymes. In green enzymes active towards the backbone of the polysaccharide are indicated, while in black exo-active and substitution removing enzymes are shown. Hydroxycinnamic acid substituents, such as ferulic acid, are not depicted in this figure, as these structural compounds are only generic for grass xylans. Hence, ferulic acid esterases are not included as well.

Examples of such accessory enzymes, produced by fungi, are pectin methylesterases (CE8) and rhamnogalacturonan acylesterases (CE12). In addition, a whole array of arabinan degrading GHs (GH3, 43, 51, 54, 62, 93) and galactan degrading GHs (GH3, 30, 43, 53) are available from fungi to fully degrade pectin side chains. Feruloyl esterases (some of which are members of CE1, but most are not included in the CAZy family system) are active towards the feruloyl-ester that is present on the pectic arabinan and galactan side-chains found in various sources like sugar beet and potato (Kühnel *et al.*, 2012; Ralet *et al.*, 1994; Wefers *et al.*, 2014). Enzymes like xylogalacturonan hydrolase and specific exo-polygalacturonases, which can cleave the xylogalacturonans backbone rather than remove the xylosyl substituents, can be found in GH28, whereas RG-II degrading enzymes have hardly been reported in literature (Gilbert *et al.*, 2008; Zandleven *et al.*, 2005).

Fungi usually produce various members of the above mentioned GH families, although many of these enzymes have not yet been biochemically characterized. Such a plethora of pectin degrading enzymes (per fungal strain) shows the complexity of plant pectic structures resulting in the requirement for a large variety of enzymes needed for complete degradation. To give an example, *A. niger* produces seven different endo-PGs, of which each shows distinct kinetic properties, sensitivity for HG methyl esterification and processivity capabilities (Bussink *et al.*, 1992; de Vries *et al.*, 2017; de Vries and Visser, 2001). The same fungus has six RHGs in its genome, of which two are characterized showing different product profiles resulting from degradation of substituted RGs indicating a different substrate specificity of these enzymes (de Vries *et al.*, 2017; Suykerbuyk *et al.*, 1997).

In addition to the hydrolytic backbone degrading enzymes, pectin (PL1) and pectate lyases (PL1, 3, 9) cleave the methyl esterified HG backbone and non-esterified HG, respectively, while rhamnogalacturonan lyases (PL4, 11) act towards the RG backbone. The lyases act via a β -elimination mechanism, resulting in cleavage and double bond formation between the C4 and C5 of the non-reducing end product. These fungal lyases have been characterized to a limited extent (Benen and Visser, 2003; Limberg *et al.*, 2000; Remoroza *et al.*, 2014). A characterized PL4 rhamnogalacturonan lyase from *Aspergillus aculeatus* preferably cleaves the glycosidic linkage next to the fourth residue counted from the reducing end L-rhamnosyl residue and is severely affected by backbone acetylation and the presence of longer side chains that are attached to the neighboring rhamnose (Mutter *et al.*, 1994).

The PL formed unsaturated double bond could possibly be hydrated and cleaved by enzymes that are members of GH105 (unsaturated rhamnogalacturonan hydrolases) (Lombard *et al.*, 2014). Unfortunately, the characterization of these hydrolases from fungi is lacking, although several putative candidates have been identified.

Characterized enzymes are not only relevant for assessing (new) industrial applications, as discussed at the end of this chapter, but they can also serve as tools to characterize pectic structures via so-called enzymatic fingerprinting (Limberg *et al.*, 2000; Remoroza *et al.*, 2014).

Xylan Degrading Glycoside Hydrolases

Xylans are a diverse group of polysaccharides, although all have a backbone of β -(1 $\rightarrow$ 4)-linked xylosyl residues. Cell wall xylans can comprise 20%–30% (w/w) of the dry matter content in dicots, such as hardwoods, and up to 50% (w/w) in cereals and grasses (Ebringerová *et al.*, 2005). The latter monocotyledonous heteroxylans are further substituted by arabinosyl residues at generally O3, or both O2 and O3 backbone xylosyl positions, and are therefore named as “arabinoxylan” (Fig. 5; Kabel *et al.*, 2002a,b; Rogowski *et al.*, 2015). To a lesser extent, these xylans can be substituted via O2 of the xylosyl residues by (4-O-methyl-) glucuronosyl and/or acetyl groups, via the O2, O3 or both positions ((acetylated)glucuronarabinoxylan (GAX)) (Fig. 5; Kabel *et al.*, 2002a,b; Rogowski *et al.*, 2015; Smith *et al.*, 2017). The arabinosyl substituents can be further esterified at their O5 position to ferulic or diferulic acid and, although in much lesser extent, to *p*-coumaric acid (Appeldoorn *et al.*, 2013). Glucuronoxylan (GX) is

found in hardwoods, whereby the xylan backbone is ramified with α -(1 $\rightarrow$ 2)-linked 4-O-methyl-glucuronosyl residues and is highly acetylated (Kabel *et al.*, 2003; Rogowski *et al.*, 2015).

The xylan backbone is degraded by endo- β -1,4-xylanases (mainly in GH10, 11, 30; Fig. 5) and the released xylo-oligosaccharides are further degraded by β -xylosidases (GH3, 43, 54; Table 1). In particular for GH10 and GH11 endo-xylanases, it has been shown that due to the enzyme and its characteristic catalytic site structure, they vary in mode-of-action towards decorated xylans, i.e., arabinoxylan and glucuronoxylan (Kolenová *et al.*, 2006; Kormelink *et al.*, 1993a; Pell *et al.*, 2004; Pollet *et al.*, 2010; Verbruggen *et al.*, 1998). To be more specific, members of the GH10 family, such as endo-xylanase I from *Aspergillus awamori*, can cleave directly next to a glucuronosyl or arabinosyl substituted xylosyl residue at the non-reducing end site (Kolenová *et al.*, 2006; Kormelink *et al.*, 1993a,b; Kormelink and Voragen, 1993; Pell *et al.*, 2004; Verbruggen *et al.*, 1998). Enzymes from this GH10 family have a “salad bowl” like shape and are able to bind substituted xylan in such a way that catalytic cleavage on the non-reducing end directly next to the substituted xylosyl is favored (Pell *et al.*, 2004). In contrast, the activity of members from GH11, recognized by their half open right hand shape-like structure, towards substituted xylan is more hindered and, therefore, their catalysis result in both larger oligosaccharides and oligosaccharides having a free (non-substituted) xylosyl residue on the non-reducing end (Kormelink *et al.*, 1993a,b; Pollet *et al.*, 2010; Verbruggen *et al.*, 1998). In addition to xylan substitution, also xylan solubility might affect the catalytic performance of GH10 and GH11 endo-xylanases differently, as for example has been shown for endo-xylanases from *M. thermophila* C1 (van Gool *et al.*, 2013).

To accommodate xylan degradation, fungi produce, in addition to the endo-xylanases, usually a variety of xylan-debranching enzymes. As most plant xylans are branched with arabinosyl or (4-O-methyl-) glucuronic acid residues or acetyl esters or a combination hereof, three main debranching enzyme classes are α -arabinofuranosidases (e.g., family GH43, 51, 54 etc.), α -glucuronidases (e.g., family GH67 or GH115), and acetylxyylan esterases (CE1) (Table 1) (Biely *et al.*, 2014; Ryabova *et al.*, 2001; Sørensen *et al.*, 2006; van den Brink and de Vries, 2011). Esterases are the least specific from these three groups, although characterized members of CE1 vary in their ability or preference to attack single substituted xylosyl residues, O2- or O3-acetylated, and double substituted xylosyl residues, acetylated at both O2- and O3-positions (Neumüller *et al.*, 2015). In addition, some CE1 members are shown to act as feruloyl esterases, which is not further discussed in this chapter (Dilokpimol *et al.*, 2016). Note that acetyl xylan esterases can have a specificity for acetylated xylan over other acetylated polysaccharides, such as acetylated pectin (Biely *et al.*, 2014).

Many of the GH51 arabinofuranosidases cleave off arabinose from xylosyl residues having only one arabinosyl substituent (O3-linked) (Murciano Martínez, 2016; Sørensen *et al.*, 2006). Recently, in the case of the bacterial XacAbf51, for the first time a GH51 member shows the ability to cleave off O3-linked arabinosyl from xylosyl residues having also the O2-position coupled to an arabinosyl residue (Dos Santos *et al.*, 2018). So far, for fungal enzymes, this feature has only been described for a few GH43 members (Sørensen *et al.*, 2006). Like for GH51 arabinofuranosidases, GH62 candidates have been shown to hydrolyze arabinose from single substituted xylosyl residues (Wilkens *et al.*, 2017). While in the same family candidates were found to be active towards both arabinoxylan and pectic L-arabinan, their activity towards the former polysaccharide was generally higher than for L-arabinan. The recently suggested subfamily classification of GH62, might further distinct substrate specifics within this family, although, hereto, more GH62 candidates will need to be characterized (Wilkens *et al.*, 2017).

α -Glucuronidases are another example for which their structure, conserved in either the GH67 or the GH115 family, steers the ability to cleave off glucuronic acid substituents only from specific positions (Rogowski *et al.*, 2014). In basidiomycetes, GH115 prevails over GH67, which is for example shown by genomes of 38 different basidiomycetes in which only genes encoding GH115 are described (Rytioja *et al.*, 2014). For ascomycetes, like for various *Aspergillus* strains, genes encoding both GH115 and GH67 α -glucuronidases are apparent (Rytioja *et al.*, 2014).

The GH67 glucuronidases have frequently been shown to be able to release both glucuronic acid and 4-O-methylglucuronic acid, but only from non-reducing end xylosyl residues, i.e., in oligosaccharides (Murciano Martínez *et al.*, 2016). GH115 glucuronidases, although only a few fungal members have been described in literature, have the same ability, but are significantly more active against substrates in which the xylosyl residues, decorated with (4-O-methyl-)glucuronic acid, is flanked by one or more xylose residues (Chong *et al.*, 2011; Murciano Martínez *et al.*, 2016; Rogowski *et al.*, 2014). Interestingly, some of these GH115 glucuronidases, but not all, are active towards both oligomeric and polymeric glucuronoxylan structures (Murciano Martínez *et al.*, 2016; Rogowski *et al.*, 2014).

Mannan Degrading Glycoside Hydrolases

Mannans and glucomannans mainly consist of β -(1 $\rightarrow$ 4)-linked mannosyl units, which can be O2 and O3 acetyl-esterified, as found in coffee beans, ivory nut, but also sugar beet and soy bean (Singh *et al.*, 2018). Next to these mannosyl units, the backbone can also contain glucosyl units as reported for cell wall glucomannans, and for glucomannans present as storage polysaccharides (e.g., konjac tuber) (Berglund *et al.*, 2018). Galactomannans having a varying level of galactosylation of the mannan backbone can be found as storage polysaccharides in seeds from the locust bean tree, guar tree and cassia tree (Wielenga, 2009).

In cell walls of softwoods, O-acetylated (galactogluco)mannan comprises up to 25% of the wood dry weight (Berglund *et al.*, 2018). Hardwoods contain less mannan (3%–5%), which is in general not galactosylated, but may be acetylated (Gilbert *et al.*, 2008).

Enzymes that are involved in the degradation of mannans are β -mannanases (e.g., family GH5, 26, 134) and β -mannosidases (GH1, 2 and 5; Table 1) (Gilbert *et al.*, 2008; Shimizu *et al.*, 2015), and these enzymes have been described in full detail by others (Ademark *et al.*, 2001; Aulitto *et al.*, 2019; Von Freiesleben *et al.*, 2018).

Fig. 6 General reaction of C1- and C4-oxidizing LPMOs, resulting in cleavage of the glycosidic linkage and either δ -lactones or 4-ketoaldoses are formed (Quinlan *et al.*, 2011). The δ -lactones convert in water to aldonic acids, while 4-ketoaldoses are, in water and pH dependent, in equilibrium with their geminal diol form (Bey *et al.*, 2013; Phillips *et al.*, 2011; Quinlan *et al.*, 2011).

Lytic polysaccharide monooxygenases (LPMOs)

The discovery of lytic polysaccharide monooxygenases (LPMOs), oxidizing polysaccharides resulting in subsequent glycosidic bond cleavage, has majorly revisited the concept of enzymatic (ligno-)cellulose degradation (Vaaje-Kolstad *et al.*, 2010). In contrast to the GHs discussed above, LPMOs require oxygen (or hydrogen peroxide) and an electron donor to result in oxidative cleavage (Kracher *et al.*, 2016; Bissaro *et al.*, 2017). Although LPMOs seem to have relatively low turnover numbers, they increase the substrate accessibility for other enzymes and have been shown to boost the activity of hydrolytic enzyme cocktails (Müller *et al.*, 2015). Therefore, nowadays, LPMOs are considered essential and even indispensable assets for (ligno-)cellulose conversions (Frommhagen *et al.*, 2015, 2018).

The first two LPMO families, created in the CAZy database around 2013, were classified as Auxiliary Activities (AA; AA9 and AA10), while before that year LPMOs were erroneously classified as GH61 (or CBM33 with mainly bacterial candidates) as their oxidative mechanism was not yet established (Quinlan *et al.*, 2011). Fungal AA9 LPMOs have been shown to result in cellulose chain cleavage due to oxidation of the glucosyl residues (Fig. 6) at the C1 position (EC 1.14.99.54, lytic cellulose monooxygenase (C1-hydroxylating)) or at the C4 carbon position (EC 1.14.99.56, lytic cellulose monooxygenase (C4-dehydrogenating)) (Frommhagen *et al.*, 2016; Phillips *et al.*, 2011). In addition, certain fungal members of the AA9 family have no strict so-called regioselectivity, resulting in both C1- and C4-oxidised oligosaccharides (Frommhagen *et al.*, 2016; Hemsworth *et al.*, 2015; Li *et al.*, 2012; Vaaje-Kolstad *et al.*, 2017). AA10 LPMOs, mainly comprising bacterial and no fungal candidates, act towards chitin (EC 1.14.99.53, lytic chitin monooxygenase) and cellulose (both EC 1.14.99.54 and EC 1.14.99.56) (Jensen *et al.*, 2019). Within the past years, new LPMO families have been added, all containing fungal members: AA11 active towards chitin and, possibly, cellulose (so far only one fungal member has been characterized, which is only active towards chitin (Hemsworth *et al.*, 2014)), AA13 active towards starch (EC 1.14.99.55 lytic starch monooxygenase). Most recently, AA families (AA14–16) have been added with so far zero, one or two biochemically characterized fungal members, hence, substrate specificities and regioselectivity have yet to be further explored for these families (see for example reviews from Chylenski *et al.*, 2019; Frommhagen *et al.*, 2018; Tandrup *et al.*, 2018).

In general, the catalytic activity of LPMO relies on a surface-exposed mono-copper-dependent active site. The copper ion is coordinated by three nitrogen atoms that are part of the histidine-brace composed of two conserved histidine residues, of which one is the N-terminus (Frandsen *et al.*, 2016; Quinlan *et al.*, 2011; Tandrup *et al.*, 2018). This N-terminal histidine is usually methylated in homologously expressed fungal LPMOs (Li *et al.*, 2012; Quinlan *et al.*, 2011). In contrast, bacterial LPMOs and LPMOs produced in heterologous hosts, such as the methylotrophic yeast *Pichia pastoris*, do not have the additional methylation at the N-terminal histidine (Hemsworth *et al.*, 2015; Li *et al.*, 2012). The presence of methylation of the N-terminal histidine has been suggested to improve the stability of LPMOs (Petrović *et al.*, 2018). However, LPMO members with or without methylation of the N-terminal histidine have been active (Borisova *et al.*, 2015; Westereng *et al.*, 2011), indicating that the role of this N-terminal methylation remains unclear.

In this section, we will further mainly discuss the largest fungal LPMO family to date, being CAZy family AA9, active towards β -(1 $\rightarrow$ 4)-linked glucosyl bonds in polysaccharides and, to a certain degree, in oligosaccharides. The first fungal AA9 LPMO with

shown C1- and C4-regioselectivity, or in this case nonselectivity, was TaGH61 from *Thermoascus aurantiacus* (Quinlan *et al.*, 2011; Fig. 6). Such C1-oxidation of glucosyl residues in cellulose leads, after cleavage of the glycosidic bond, to the formation of an unstable δ -lactone (-2 Da), which is converted into an aldonic acid in the presence of water ($+16$ Da) (Frommhagen *et al.*, 2016; Sun *et al.*, 2020a; Vaaje-Kolstad *et al.*, 2010; Fig. 6). Oxidation of the C4-carbon of the glucosyl residues in cellulose results, after cleavage, in the formation of a more stable 4-ketoaldose (-2 Da) that might tautomerizes into a geminal diol ($+16$ Da) depending on the pH (Quinlan *et al.*, 2011; Sun *et al.*, 2020a; Westereng *et al.*, 2016). Currently, the number of AA9 LPMOs with biochemically analyzed C1/C4-regioselectivity is growing rapidly (Frommhagen *et al.*, 2018).

A main difference with GH structures is that AA9 LPMOs have no substrate binding pocket, but have a distinct flat binding surface around the exposed active site copper atom (Borisova *et al.*, 2015; Frandsen *et al.*, 2016; Tandrup *et al.*, 2018). The exact amino acid residues responsible for the substrate binding, however, are still unknown. Nevertheless, it can be expected that specific substrate recognition and regioselectivity of LPMOs relate to how the LPMO's flat binding surface binds to the substrate (Borisova *et al.*, 2015; Li *et al.*, 2012). Depending on the substrate specificity, these surface exposed binding loops (segments) comprise various hydrophilic and aromatic residues (Laurent *et al.*, 2019). The fact that AA9 LPMOs not only oxidatively cleave cellulose, but certain fungal AA9 members also act towards soluble cellooligosaccharides (Isaksen *et al.*, 2014) and hemicellulosic xyloglucan (Borisova *et al.*, 2015; Frommhagen *et al.*, 2018), shows that substrate binding is the result of the presence of specific loops or segments rather than binding to single amino acids (i.e., tyrosines). Even xyloglucan active AA9 LPMOs have been described to act towards xyloglucan independent of the side chains attached to the β -(1 $\rightarrow$ 4)-linked glucan backbone, like FgLPMO9A and GtLPMO9A-2 (Kojima *et al.*, 2016; Nekiunaite *et al.*, 2016), whereas others oxidize xyloglucan more specifically, such as NcLPMO9C and MtLPMO9J (Agger *et al.*, 2014; Kadowaki *et al.*, 2018; Laurent *et al.*, 2019; Sun *et al.*, 2020b).

Overall, more and more LPMOs will become biochemically characterized, for their substrate specificity and regioselectivity, to further contribute to the understanding of their function in nature and for commercial applications. As many fungi are known to comprise a large number of LPMOs in their genome, for example 22 putative AA9 LPMOs for *M. thermophila* C1 (Berka *et al.*, 2011), and between 9 and 33 for 18 reported basidiomycetes, for example 33 for *Coprinopsis cinerea* (Rytioja *et al.*, 2014), a further diversification in function of AA9 LPMOs can be expected.

Relevance for Industry

Many drawbacks of chemical transformation processes used in various industries can be overcome by introducing an enzymatic conversion process (reviewed by i.e., Chapman *et al.*, 2018; Alkorta *et al.*, 1998; Singh *et al.*, 2016). For example, nonspecific (chemical) reactions might result in undesired side-products, while enzymes often catalyze reactions with a high specificity. In addition, enzymes are known to react well at moderate temperatures, hence, processes might run at lower temperatures and/or lower pressures than otherwise needed to drive reactions. Such lower energy costs are beneficial both from a commercial and environmental point of view. A similar reasoning can be applied to processes needing harsh or even hazardous conditions, i.e., high temperatures, pressures, use of toxic catalysts, and acid or alkaline catalysts. Obviously, to enable application in food products applied enzymes should be food grade or "Generally Recognized As Safe" (GRAS), which is, at least in the European Union, not needed if the enzymes are only used in the process and do not end up in the final food product (Sewalt *et al.*, 2016).

Moreover, with the current possibilities of recombinant DNA technology and protein engineering, it became possible to target production of specific enzymes or combinations of enzymes by genetically modified commercial microbial production hosts. Such engineering developments have led to improvements in the stability, economy, specificity, and overall application potential of industrial enzymes. Hence, seen the above-mentioned benefits of using enzymes, it is not surprising that the number of commercial applications of enzymes is increasing every year (Chapman *et al.*, 2018).

Five major world markets for industrial enzymes can be distinguished: house hold care (i.e., detergents), food and beverages, biorefinery, feed and various technical applications (Chapman *et al.*, 2018; Singh *et al.*, 2016). In particular in the food and beverages, biorefinery and feed industry, carbohydrate active enzymes play a major role.

In the food and beverage industry, carbohydrate active enzymes have contributed to i.e., safer processes, higher yields and products with improved quality. Well-known examples are (1) the implementation of starch degrading enzymes to convert starch into dextrins and glucose for confectionery purposes, replacing hazardous highly acidic processes (Monteiro de Souza and de Oliveira Magalhães, 2010; van der Maarel *et al.*, 2002); (2) pectinases in the fruit juice industry for clarification reactions and higher yields (Alkorta *et al.*, 1998); (3) in the baking industry amylases and/or xylanases can be used to improve the dough stability, texture, volume and color, and may contribute to a prolonged freshness of breads (Markets-reports, 2014; Singh *et al.*, 2016). Feed digestibility has been shown to be improved when (hemi-)cellulose or pectin degrading enzymes, depending on the composition of the feed, are added to the feed (de Vries and Gerrits, 2018; de Vries *et al.*, 2012; Pustjens *et al.*, 2014; Torres-Pitarch *et al.*, 2019). Moreover, released pectic structures and formed non-digestible oligosaccharides are considered to contribute to the health of the animals due to either direct interactions with the gut tissue resulting in immunomodulating effects (Meijerink *et al.*, 2018; Sahasrabudhe *et al.*, 2018) or due to their growth stimulation effects of beneficial intestinal microflora (Akbari *et al.*, 2017; Tian *et al.*, 2017). The latter role has also been attributed to (human) milk oligosaccharides (Albrecht *et al.*, 2010), protecting babies and young animals in their first years and possibly beyond (Difilippo *et al.*, 2016). Currently, in infant milk formula, transglycosylating galactosidase produced galacto-oligosaccharides are added to take over the function of these milk

oligosaccharides that are yet too complex to produce at commercial scale (Alizadeh *et al.*, 2016; Difilippo *et al.*, 2016; Elwakiel *et al.*, 2018; Ladirat *et al.*, 2014a,b).

Biorefinery processes aim to upgrade agricultural biomass or food industrial side-streams, for example by their conversion into biofuels and biochemicals. Hereto, the polysaccharides need to be converted, mostly enzymatically, into (fermentable) glucose and other monosaccharides (Kabel *et al.*, 2017). In this chapter, it has been reviewed that such biomass streams are largely composed of cellulose and hemicellulosic xylan (i.e., bran, straw, stover), while other industrial by-products are richer in xylo-glucan and pectin (i.e., sugar beet pulp, potato peel pulp). Their conversion requires not only a defined and well-combined set of, preferably synergetic, enzyme activities, but biorefinery processes will also benefit from robust (i.e., thermostable) enzyme cocktails (Haki and Rakshit, 2003).

To further boost the number of commercial applications of enzymes and to improve existing (fungal) enzyme cocktails, fungi and their enzymes represent an unlimited pool of possible candidates (Benoit *et al.*, 2015; de Vries *et al.*, 2017; van den Brink and de Vries, 2011). However, although many fungal genomes have been sequenced and annotated, and many genes seem to putatively encode carbohydrate active enzymes (Lombard *et al.*, 2014), only a relatively low number of candidates have been biochemically characterized. Future enzymatic applications, hence, depend on the push to characterize carbohydrate active enzymes, not only for their environmental activity and stability, but also for their exact mode-of-action on natural plant polysaccharides.

Introduction

Carbohydrates are classified according to their degree of polymerization (DP), which is the number of units composing the molecule. According to IUPAC classification, they can be divided in monosaccharides (DP 1), oligosaccharides (DP 2–9) and polysaccharides (DP ≥ 10) (McNaught, 1996).

Based on the physiological properties, carbohydrates can be classified as digestible or non-digestible. Normally, non-digestible oligosaccharides are classified as prebiotics, and according to the International Scientific Association for Probiotics and Prebiotics (ISAPP), a prebiotic is a substrate that is selectively utilized by host microorganisms to confer health benefits (Gibson *et al.*, 2017). They remain undigested in the upper gastrointestinal tract, i.e., they are resistant to hydrolysis by human saliva, gastric and pancreatic juices, and are not absorbed in the small intestine, reaching the colon where they are available for utilization by probiotics (Meyer *et al.*, 2015).

Fungi are especially attractive producers of enzymes for the production and commercialization of oligosaccharides. They are able to secrete the enzymes, which allows for greater stability and makes the production process significantly cheaper (Lange, 2017). Besides the use of free fungal enzymes, oligosaccharides can be produced directly by the mycelium or by immobilized fungal cell and enzymes (Fig. 1).

This chapter emphasizes the main types of oligosaccharides and their properties, natural sources, modes of production and potential industrial applications.

Fructooligosaccharides

Fructooligosaccharides (FOS) are oligomers of β (2-1)-linked D-fructose molecules with a maximum DP of 10. FOS can contain one molecule of glucose in their structure to form a linear chain linked to fructose (GF_n) or only fructose (Fn) (Yildiz, 2011). GF_n are mainly derived from the transfructosylation of sucrose while Fn are derived from inulin hydrolysis (Dominguez *et al.*, 2014). The smallest FOS is kestose (1-kestose, β -D-fructofuranosyl-(2 → 1)- β -D-fructofuranosyl-(2 → 1)- α -D-glucopyranoside). In addition to kestose, nystose (one glucose and three fructose molecules) and fructosyl nystose (one glucose and four fructose molecules) are the most common GF_n molecules (Fig. 2). They are also referred as GF2, GF3, and GF4, respectively. Regarding Fn, it is denominated inulo(latin of polymerization degree)ose, such as inulotriose, inulotetraose, etc. (Yildiz, 2011).

The enzymes involved in FOS production are mainly invertases and inulinases. Invertase or β -fructofuranosidase (EC 3.2.1.26) catalyzes the hydrolysis of sucrose to produce an equimolar solution of fructose and glucose. In high sucrose concentrations, some β -fructofuranosidases can have transfructosylating activity, transferring fructose to sucrose, producing GF_n. The β -fructofuranosidase with this specific activity is named fructosyltransferase (EC 2.4.1.9) (de Almeida *et al.*, 2018). Endoinulinases (EC 3.2.1.7) hydrolyze internal β -2,1 fructofuranosidic linkages of inulin releasing mainly inulotriose, inulotetraose and inulopentose as products (Singh *et al.*, 2020).

In industry, the most common process for FOS production is sucrose biotransformation by transfructosylation catalyzed by β -fructofuranosidases from the ascomycete fungal species *Aspergillus*, *Aureobasidium* or *Penicillium* (USDA, 2015; Sánchez-Martínez *et al.*, 2020). After enzymatic reaction, the products pass through downstream processes, including removal of reducing sugars (using the yeast *Pachysolen tannophilus*), decolorization and removal of organic impurities by activated carbon, clarification by microfiltration, purification using ion-exchange to remove color and ash components, and evaporation and concentration to yield FOS sirup. Concentrated FOS sirup is pasteurized and can be packaged as sirup or submitted to a spray drying process to be sold as a white powder (FDA, 2015; Soni and Tsai, 2016).

In 1984, Meiji Seika Co. in Japan was the first to succeed in the commercial production of FOS. They used invertase from *Aspergillus niger* to produce the products Neosugar® and Meiligo® (Yun, 1996; Dominguez *et al.*, 2014). Nowadays, several FOS are commercialized as prebiotics. Some are derived from sucrose, such as NutraFlora®, Actilight®, Profeed®, Oligo-sugar and Beneshine™P-type, while others are derived from inulin, like Orafit®, Fibrulose®, Frutalose® and olifruktinesp® (Dominguez *et al.*, 2014).

Industrial processes can be performed via a batch system using a soluble enzyme, or a continuous process using immobilized enzyme or whole cells (Sánchez-Martínez *et al.*, 2020). Examples of fungi and fungal enzymes as well as their products are shown in Table 1.

The continuous process using immobilized enzymes or cells is an alternative to the use of free enzymes. Immobilized biocatalysts are more stable, can be removed from the reaction medium and be reused many times, reducing the final cost of the enzyme and enabling greater purity of the final product (Sheldon and van Pelt, 2013). Industrial use of immobilized enzymes for

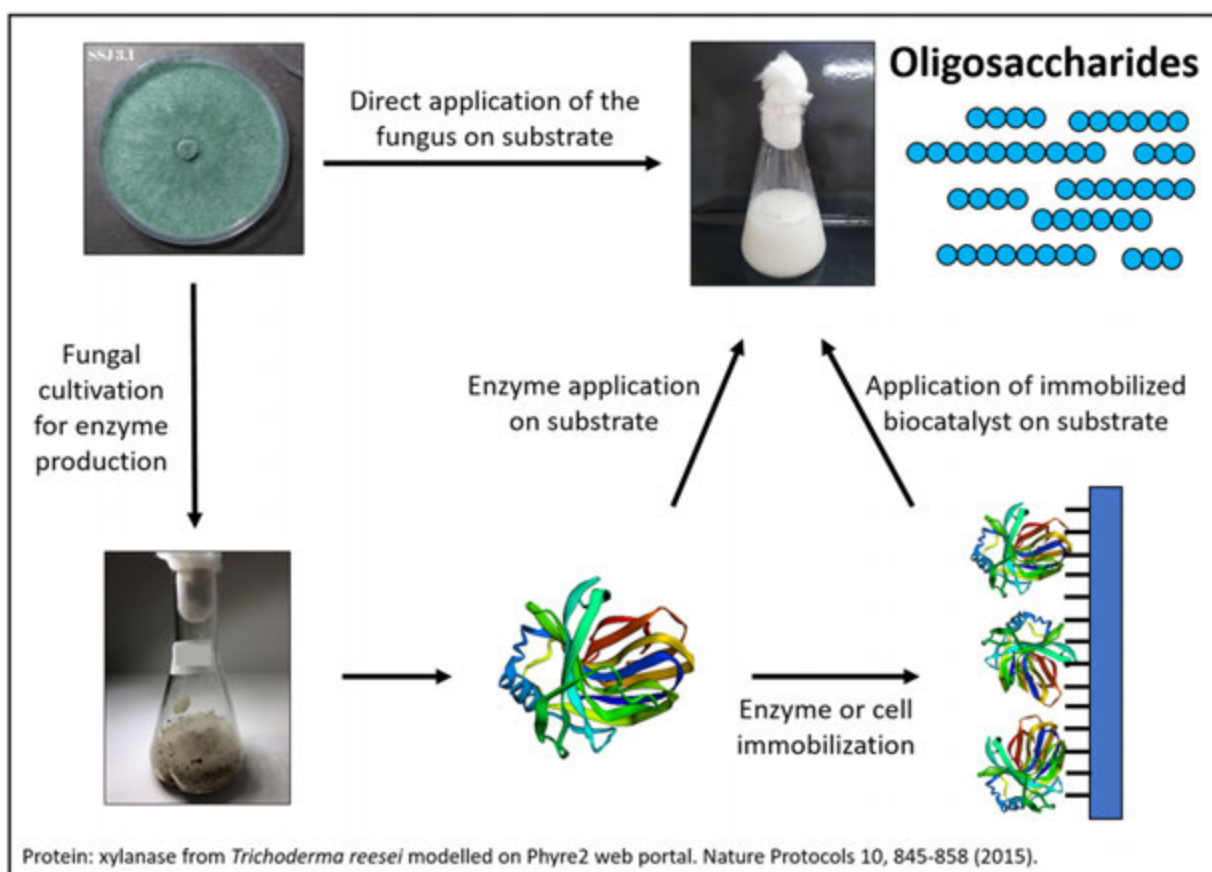

Fig. 1 Oligosaccharide production using fungi or fungal enzymes.

Fig. 2 Structures of kestose (a), nystose (b), fructosyl nystose (c) and the Fn-type fructooligosaccharide. $n \leq 5$.

FOS production has been reported using calcium alginate and polystyrene divinylbenzene ion exchange resin as a support (GRAS, 2017). An alternative is the use of mycelium with mycelia-bound enzymes. This approach minimizes activity loss during operation and allows for establishing a continuous process, as can be done with immobilized enzymes (Zambelli *et al.*, 2014).

The main application for FOS is in the food industry. They are low calorie and non-cariogenic sweeteners. As components of functional foods, FOS have “generally recognized as safe” (GRAS) status from the Food and Drug Administration (FDA) in the USA (Smith, 2002). FOS can also be used in bakery products, in acidophilus milk, creams, desserts, yogurt, ice cream, sauces and

Table 1 Production of fructooligosaccharides by fungal enzymes or mycelium

Enzyme	Organism	Immobilization material	Substrate	Main product	Yield (%) ^a	Reference
β -fructofuranosidase	<i>Aspergillus thermomutatus</i>	–	Sucrose 200 g/L	GF2, GF3	–	(Tódero <i>et al.</i> , 2019)

Immobilized cell	<i>Aureobasidium pullulans</i>	Calcium alginate	Sucrose 770 g/L	GF2, GF3, GF4	57	(Jung <i>et al.</i> , 2011)

^aYield refers to sucrose conversion considering total FOS production. G: glucose. F: Fructose.

several other food products. They can improve the organoleptic quality and provide a better-balanced nutritional composition (FDA, 2015; Sánchez-Martínez *et al.*, 2020).

FOS are considered prebiotics and their use in infant formulas is due to their positive effects on gastrointestinal function. They are reported to increase the fecal *Bifidobacterium* content to improve problems such as constipation in children that were not breast fed (Souza *et al.*, 2018). Several studies have related FOS consumption to decreased fasting blood glycaemia levels in rodents with a high-fat diet, obesity and diabetes (Le Bourgot *et al.*, 2018). FOS intake in humans has been reported to cause a significant reducing in postprandial glucose and insulin concentrations. Therefore, FOS is an interesting alternative for sugar in diets (Respondek *et al.*, 2014).

Xylooligosaccharides

Xylooligosaccharides (XOS) are sugar oligomers formed by xylose units bound via β -(1 $\rightarrow$ 4) linkages and they are called xylobiose (2 monomers), xylotriose (3 monomers), xylotetraose (4 monomers), xylopentose (5 monomers), xylohexose (6 monomers) and so on (Fig. 3) (Samanta *et al.*, 2015).

XOS are commonly found in fruits, vegetables, bamboo shoots, milk and honey and they can be commercially generated from hydrolysis of xylan (Antov and Đorđević, 2017; Mano *et al.*, 2018). Xylan is one type of hemicellulose that is the second most abundant polymer in nature and represents about 20%–40% of the dry weight of lignocellulosic materials (Malgas *et al.*, 2019). Hemicelluloses are hetero-polysaccharides composed of different sugars and are classified according to the main sugar residue of their backbone to xylans, xyloglucans, mannans, glucomannans and β -glucans (Scheller and Ulvskov, 2010).

Xylan is composed of a backbone of β -1,4-linked xylose units with diverse substituents that include different side chain carbohydrates and acids (Nordberg *et al.*, 2018). Therefore, xylan structures vary in degree of polymerization, monomeric units and types of linkages and the side groups result in branched XOS with diverse biological properties (Aachary and Prapulla, 2011; Samanta *et al.*, 2015). Commercial XOS have been produced from xylan derived from barley hulls, brewery spent grains, corn cob, corn stover, rice hulls, wheat bran, wheat straw, oat spelt and other plant biomass (Akpinar *et al.*, 2007; Jain *et al.*, 2015).

The production of XOS on an industrial scale from lignocellulosic materials rich in xylan can be performed by chemical procedures using steam, acid or alkaline solutions, enzymatic hydrolysis, or a combination of both methods (Akpinar *et al.*, 2007; Mussatto and Mancilha, 2007; Samanta *et al.*, 2015). Enzymatic degradation of xylan is more advantageous for XOS production

Fig. 3 Structure of xylooligosaccharides. $n \leq 5$.

Table 2 Fungal endoxylanases applied for xylooligosaccharide (XOS) production

Fungus	Substrate	Main XOS ^a	Reference
<i>Aspergillus flavus</i>	beechwood xylan	X2 and X5	(Chen <i>et al.</i> , 2019)
<i>Aspergillus luchuensis</i> (= <i>A. foetidus</i>)	corncoobs	X2, X3, X4 and X5	(Chapla <i>et al.</i> , 2012)

<i>Penicillium funiculosum</i>	arabinoxylan from wheat	X4, X5 and X6	(Lafond <i>et al.</i> , 2011)
<i>Talaromyces amestolkiae</i>	birchwood xylan	X2 and X4	(Nieto-Domínguez <i>et al.</i> , 2017)

^aX2, X3, X4, X5, X6 are referred to xylobiose, xylotriose, xylotetrose, xylopentose and xylohexose, respectively.

since enzymes show high specificity, no generation of undesirable byproducts and side reactions, no requirement of special equipment and facilitated recovery (Long *et al.*, 2018; Chen *et al.*, 2019; Wu *et al.*, 2019). Endoxylanases, β -xylosidases and some debranching enzymes are employed for XOS production (Jain *et al.*, 2015). However, XOS yields are dependent on the source of xylan, enzymatic activities and incubation conditions such as pH, temperature and hydrolysis time (Samanta *et al.*, 2015).

Moreover, for xylan degradation by enzymes, a pretreatment must be performed on the lignocellulosic material to allow for a better access of the enzymes to the xylan backbone (Samanta *et al.*, 2015; Long *et al.*, 2018). In this case, xylan is often extracted from lignocellulosic sources using alkaline solutions at a moderate temperature for two to three hours (Akpınar *et al.*, 2007; Linares-Pasten *et al.*, 2016). Extraction performed with hot water under high pressure is another relatively common method used before enzymatic hydrolysis (Immerzeel *et al.*, 2014).

Endoxylanases (EC 3.2.1.8) act on the xylan backbone, cleaving internal β -1,4-glycosidic linkages between xylopyranosyl residues and their products may include xylobiose, xylotriose, xylotetraose, and longer and/or branched XOS (Malgas *et al.*, 2019). β -Xylosidases (EC 3.2.1.37) are exo-acting enzymes that degrade short xylooligosaccharides, mainly to liberate xylose (Yan *et al.*, 2008). Therefore, the XOS produced by endoxylanases are further hydrolyzed into xylose by β -xylosidases and an endoxylanase without any β -xylosidase activity is desired for XOS production (Long *et al.*, 2018; Chen *et al.*, 2019). Some studies have reported enzymatic synthesis of XOS by the application of the transxylosylation activity of β -xylosidases (Aachary and Prapulla, 2011), i.e., the formation of larger xylooligosaccharides from small oligosaccharides by transfer reactions (Benassi *et al.*, 2013).

Most reports on the enzymatic production of XOS are related to fungal enzymes, especially endoxylanases. Considering an industrial scale, endoxylanases are mainly produced by *Aspergillus* sp. and *Trichoderma* sp., although *Penicillium* strains have been considered as good candidates to produce these enzymes (Pal and Khanum, 2011; Nieto-Domínguez *et al.*, 2017). Table 2 shows some examples of fungal endoxylanases applied for XOS production.

The attention given to XOS production has increased since these compounds show potential as prebiotics and the recommended XOS dose is 0.12 g/kg of body weight in adults (Oku and Nakamura, 2002). XOS are associated with several health benefits. They are able to improve bowel function (Jain *et al.*, 2015; Samanta *et al.*, 2015; Antov and Đorđević, 2017) and absorption of minerals, especially calcium, by the intestine (Swennen *et al.*, 2006; Nieto-Domínguez *et al.*, 2017; Wu *et al.*, 2019). Furthermore, XOS are associated with minimizing the risks of colon cancer (Swennen *et al.*, 2006; Jain *et al.*, 2015) and the cytotoxic effect on human leukemia cells (Ando *et al.*, 2004). XOS are also related to regulation of insulin secretion from the pancreas (Samanta *et al.*, 2015) and positive effects on type II diabetes mellitus (Sheu *et al.*, 2008), as well as lowering cholesterol (Sheu *et al.*, 2008; Wu *et al.*, 2019). Moreover, they play an important role as antioxidants and in immune modulation (Nieto-Domínguez *et al.*, 2017; Wu *et al.*, 2019).

Chito-Oligosaccharides

Chito-oligosaccharides (COS) are sugars with a degree of polymerization less than 20 produced by partial hydrolysis of the polymers chitosan or chitin. Chitin is a polymer of N-acetyl-D-glucosamine (GlcNAc) linked by β ,1-4 bonds and chitosan is the product of partial or complete deacetylation of chitin, composed of mixtures of D-glucosamine (GlcN) and GlcNAc (Fig. 4). COS can show different degrees of polymerization (DP), degrees of acetylation (DA) and pattern of acetylation (PA), especially depending on the method by which they were produced. These characteristics have a direct influence on their properties. COS with

Fig. 4 Structures of chito-oligosaccharides derived from chitin (a) and chitosan (b). $n \leq 10$.

DP less than 10 are generally soluble in water while for COS with DP greater than 10 it depends on the DA and the pH of the solution. The viscosity of COS decreases with lower molecular weight (Liaqat and Eltem, 2018; Aljbouir *et al.*, 2019).

The most common source of chitin to produce COS are crustaceans. To produce chitosan, chitin is deacetylated in an alkaline solution or enzymatically by chitin deacetylase (3.5.1.41). Chitin deacetylase releases chitosan with specific patterns of acetylated (A) and deacetylated (D) saccharides (Naqvi *et al.*, 2016). The chitin deacetylase from the nematophagous fungus *Pochonia chlamydosporia* initially deacetylates pentamers at the penultimate GlcNAc residue from the non-reducing end (ADAAA), and then deacetylates the next residue producing di-deacetylated pentamer (ADDAA) (Aranda-Martinez *et al.*, 2018). The basidiomycete fungus *Coprinopsis cinerea* has been shown to produce three chitin deacetylases (CDA1, CDA2, CDA3). The three enzymes have activities on chitobiose and CDA3 presented the highest activity against chitopentaose. CDA1 removed an acetyl group from the non-reducing end, CDA2 from the reducing end and CDA3 was able to act at either the reducing end or the nonreducing end (Bai *et al.*, 2020).

For enzymatic production of COS, chitinases are the most specific enzymes. Endochitinases (E.C. 3.2.1.14) randomly hydrolyze chitin within the chain to produce low molecular weight oligosaccharides (Kidibule *et al.*, 2018). The chitinase from the ascomycete *Trichoderma harzianum* hydrolyzed colloidal chitin and produced a fully acetylated series of COS (DP 1–4), mainly disaccharide. When chitosan was the substrate, the most abundant product was trisaccharide, presenting the acetylated residue at the reducing end (DDA) (Kidibule *et al.*, 2018).

Enzymes that preferably hydrolyze chitosan instead of chitin are named chitosanase (EC 3.2.1.132). Several fungi have been reported to produce chitosanase, including *Aspergillus fumigatus* (Zhou *et al.*, 2020), *Penicillium janthinellum* (Nguyen *et al.*, 2014), *Trichoderma koningii* (da Silva *et al.*, 2012) and *Fusarium solani* (Shimosaka *et al.*, 1993). These enzymes show differences with regards to their mode of action (endo or exo) and their specificity in degree of deacetylation of the chitosan. The enzyme from the ascomycete *Alternaria alternata* showed specificity for chitin hydrolysis, however the activity was even greater for partially deacetylated chitins. Due to this standardization of hydrolysis sites, the enzyme was denominated chitinase (Kohlhoff *et al.*, 2017).

Other non-specific enzymes like cellulases, lysozyme, protease and amylase were also effective for chitin depolymerization (Lv *et al.*, 2016; Öhlknecht *et al.*, 2017). Because commercial cellulases are more available than chitinases and chitosanases, COS are commonly produced using cellulases. Cellulases from *A. niger* (Xie *et al.*, 2010), *Trichoderma longibrachiatum* (Tegl *et al.*, 2016) and from *Trichoderma viride* (Wu and Tsai, 2004) showed to be effective for chitin depolymerization.

Production of COS from low molecular weight chitosan directly by fungi was reported for a strain of *Aspergillus* sp. This method avoided additional steps of enzyme extraction and purification. The fungus produced a heterogeneous oligomer mixture of COS with DP(s) of 2–9 with DA 16.67%–66.67% (Embaby *et al.*, 2018).

Chitin and/or chitosan can also be extracted from the cell wall of ascomycete, zygomycete, basidiomycete and deuteromycete fungi (Pochanavanich and Suntornsuk, 2002). This approach is an alternative to obtain COS from a non-animal source. Fungi are routinely used in industry to produce proteins, organic acids and secondary metabolites, and their wastes can be used for COS production. The mycelium of the zygomycete *Rhizopus oligosporus* was hydrolyzed by chitinases from the archaeon *Pyrococcus furiosus* and *T. viride* and a chitosanase from the bacterium *Streptomyces* sp. Digestion by chitosanase achieved 67% digestibility, while chitinases from *P. furiosus* and *T. viride* yielded 35% and 36%, respectively (Mahata *et al.*, 2014).

Among the biological applications attributed to COS, the antimicrobial effect obtained by fungal enzymes can be highlighted. Antimicrobial effects of COS have different results depending on COS molecular weight, degree of acetylation, concentration and mainly the target microorganism. COS produced by chitosanase from *Aspergillus fumigatus* effectively inhibited the growth of several phytopathogenic fungi, i.e., *Botrytis cinerea*, *Fusarium graminearum*, *Alternaria alternata*, *Magnaporthe grisea*, *Erysiphe cichoracearum* and *Alternaria solani*. The COS solution consisted on a mixture of disaccharides, trisaccharides and tetrasaccharides (Zhou *et al.*, 2020). Besides the antimicrobial effect, COS can also activate immune response to pathogens on plants, which opens the possibility for their use as a biocide in agriculture. In rice, the chitin-elicitor binding protein, the receptor that starts signal transduction and triggers immune response, specifically binds long-chain COS, such as heptamer-octamer (Hayafune *et al.*, 2014).

Fig. 5 Structures of galacto-oligosaccharides with $\beta(1,2)$ (a), $\beta(1,3)$ (b), $\beta(1,4)$ (c) and $\beta(1,6)$ (d) linkages. $1 \leq n \leq 6$.

In contact with *Staphylococcus aureus*, COS presenting DP > 12 caused clustering and later lysis of the cells (Li *et al.*, 2014). When the inhibitory effect of COS on the bacteria *Escherichia coli* (gram negative) and *Listeria monocytogenes* (gram positive) was compared, *E. coli* was more sensitive (Sánchez *et al.*, 2017).

Galacto-Oligosaccharides

Galacto-oligosaccharides (GOS) are soluble sugars derived from the conversion of lactose by β -galactosidases (Canfora *et al.*, 2017). β -D-Galactosidase (β -D-galactoside galactohydrolase, EC 3.2.1.23), most commonly known as lactase, catalyzes the hydrolysis of lactose $\beta(1 \rightarrow 4)$ linkages to produce glucose and galactose. This enzyme also shows transgalactosylation activity, which means the ability to transfer the galactose from lactose cleavage to a galactose from another lactose, yielding GOS (Park and Oh, 2010). GOS are short-chain carbohydrates formed by two to seven molecules of galactose and one terminal glucose molecule (Fig. 5) (Otieno, 2010; Torres *et al.*, 2010). The final products show several types of glycosidic linkages such as $\beta(1,2)$, $\beta(1,3)$, $\beta(1,4)$ and $\beta(1,6)$, and branched glucose residues may occur (Macfarlane *et al.*, 2008; Otieno, 2010). GOS naturally occurs in mammalian milk, especially in human milk, and to a smaller extent in cow's milk (Alander *et al.*, 2001).

β -Galactosidases are one of the most useful enzymes in the dairy industry to hydrolyze lactose to produce lactose-free milk products, in addition to GOS production (Kim *et al.*, 2004a,b). GOS can also be produced by chemical synthesis, but enzymatic synthesis is preferred (Otieno, 2010). Dairy products such as cow's milk, but mainly whey-derived lactose and pure lactose solutions, are the most used for GOS production by β -galactosidases (Macfarlane *et al.*, 2008; Otieno, 2010).

Because β -galactosidases are inhibited by the products galactose and glucose, the major difficulty for GOS production is the complete hydrolysis of lactose (Kim *et al.*, 2004a,b). The transgalactosylation reaction for GOS production normally occurs at high lactose concentration (Hsu *et al.*, 2007), and when GOS are produced glucose inhibition is more influential because galactoses are consumed in the process. Therefore, β -galactosidases that show low inhibition by glucose are more desirable for GOS production (Kim *et al.*, 2004a,b; Park and Oh, 2010). Moreover, an increase in GOS production is observed when β -galactosidases are mixed with glucose oxidases, which remove glucose as a byproduct (Hsu *et al.*, 2007; Park and Oh, 2010).

GOS are one of the most common oligosaccharides used as food ingredients (Tokošová *et al.*, 2015). The GOS production yield depends on lactose concentration, but also the reaction temperature, enzyme source and activity and the product length (Otieno, 2010; Meyer *et al.*, 2015). Furthermore, different microorganisms yield different oligosaccharide compositions in terms of degree of polymerization (Otieno, 2010; Tokošová *et al.*, 2015).

β -Galactosidases produced by fungi are interesting because of their extracellular character, higher thermal tolerance and lower pH-interval of activity (Gargova *et al.*, 1995). An extracellular β -galactosidase from *Aspergillus lacticoffeatus* was able to produce GOS when either whole cells or the crude enzyme was used as a biocatalyst (Cardoso *et al.*, 2017). When several fungal species for β -galactosidase activity and GOS production were tested, the ascomycetes *Aspergillus brasiliensis*, *Aspergillus restrictus*, *Aspergillus uvarum*, *Penicillium brevicompactum*, *Penicillium italic* and *Penicillium spinulosum*, the zygomycete *Mucor* sp. and the basidiomycete *Trametes versicolor* were shown to be able to produce GOS (Silvério *et al.*, 2018). An immobilized β -galactosidase from the ascomycete fungus *Talaromyces thermophilus* showed the ability to produce GOS with a maximum yield of 34% when the degree of lactose conversion was approximately 80% (Nakkharat and Haltrich, 2006). The same β -galactosidase from *T. thermophilus* showed high GOS production with high lactose concentrations and at high temperature (Nakkharat *et al.*, 2006). Thermostable β -galactosidases are associated with high transgalactosylation yields (Park and Oh, 2010).

The increased attention given to GOS is related to their prebiotic activities, with potential application in the food industry (Torres *et al.*, 2010; Silvério *et al.*, 2018), but also for the cosmetic and pharmaceutical industries (Krutmann, 2009) and the feed and pet food industries (Torres *et al.*, 2010). They are associated with improving defecation and ammonia elimination, colon cancer prevention, mineral adsorption stimulation, and lowering cholesterol and lipids (Swennen *et al.*, 2006; Park and Oh, 2010). Compared to other non-digestible sugars, GOS show low cariogenicity, low caloric values and low sweetness, as well as better physicochemical characteristics, including stability in low pH and at high-temperature conditions (Otieno, 2010). GOS have a

GRAS status in the United States, a non-Novel Food status in the EU, and they are recognized as foods for specific health use (FOSHU) in Japan (Torres *et al.*, 2010). Infant milk formulas and specific food for elderly or hospitalized people are good options for GOS inclusion (Alander *et al.*, 2001; Otieno, 2010). It is reported that the intake of 10 g per day of GOS is considered sufficient to cause a bifidogenic effect, and the establishment of a *Bifidus* microflora in the intestine of breast-fed infants is related to the presence of GOS in human milk (Mussatto and Mancilha, 2007). GOS have been commercialized by some companies such as Yakult Honsha and Nissin Sugar Manufacturing from Japan, Corn Products Intl. from the United States, and Borculo Domo Ingredients and Clasado from Europe, and in addition to the differences in purity of GOS, there are also differences in the types of linkages present in these oligosaccharides (Torres *et al.*, 2010).

Final Considerations

Interest in oligosaccharides has increased over the last years mainly due to their use as ingredients in functional foods. Maintenance of a balanced intestinal flora has been related to the beneficial effects as anti-obesity and anti-cancer. In this context, the use of prebiotics alone or in combination with probiotics is of great interest to the health field. In addition, several effects such as antioxidant, anti-inflammatory and antimicrobial are correlated to oligosaccharides. The biological effect has been shown to depend on the oligosaccharide structure. Carbohydrate analysis techniques such as high performance liquid chromatography, high performance anion exchange chromatography, mass spectrometry and infrared spectroscopy have provided a more accurate analysis of structures and a better understanding of the correlation between structure and biological effects. The search for new fungi able to produce oligosaccharides is always an important alternative, since more stable and specific enzymes can be found. Recombinant DNA technologies for the improvement or overexpression of enzymes are also important approaches for obtaining enzymes. These innovations, as well as the improvement of bioreactors and enzymatic immobilization techniques, are increasing the efficiency and viability of industrial oligosaccharide use.

Introduction

Fungi have become one of the most important microorganisms in biotechnology. The biotechnological sector use fungi as cell factories to produce food and beverages (Dupont *et al.*, 2017), organic acids (Sahasrabudhe and Sankpal, 2001), enzymes (Sharma *et al.*, 2017a,b; Walia *et al.*, 2017) and bioactive compounds (Keller *et al.*, 2005; Kuck *et al.*, 2014). In spite of the interest, their full metabolic potential is still unknown (Kjærboelling *et al.*, 2019). Metabolism can be defined as the complete set of chemical reactions that occur in living organisms in order to maintain life, *i.e.*, a network of interconnected and interdependent chemical reactions where a metabolite is transformed through a series of intermediates reactions into another metabolite that can be used by the cell. Genome-scale metabolic models (GEMs) are used as *in silico* representation of *in vivo* metabolic reactions. GEMs allow researchers to determine the characteristics of an organism and understand, to some extent, what it is capable of doing based on its genetic information (Kitano, 2002). The first GEM model was created for the bacterium *Haemophilus influenzae* shortly after the first genome was published (Edwards and Palsson, 1999). The first GEM of the ascomycete yeast *Saccharomyces cerevisiae* was published in 2003 (Förster *et al.*, 2003b), while the development of filamentous fungal metabolic networks was delayed until the publication of their genomes. In 2008, the first GEMs of filamentous fungi, *Aspergillus niger* (Andersen *et al.*, 2008), *Aspergillus nidulans* (David *et al.*, 2008) and *Aspergillus oryzae* (Vongsangnak *et al.*, 2008) were published. From then on, the number of GEMs has increased (Brandl and Andersen, 2015), but not as fast as genomes have been sequenced (Leitch *et al.*, 2018).

On average, a typical fungal GEM contains 1138 unique metabolic reactions and 1050 ORFs (Brandl and Andersen, 2015), however, on average, fungal genomes contain more than 10,000 genes (see "Relevant Websites section"). Due to the large amount of data to consider, a full analysis of a metabolic network is only possible using computational approaches (Vlassis *et al.*, 2014). The reconstruction process starts constructing a network. Based on their functional annotation, a metabolic function is assigned automatically to each gene in the genome, after which a curator reviews the features of each reaction and the genome annotation. Only then, the network is transformed into a matrix, constraints are applied and the resulting GEM is tested. GEMs are constantly changing and curators are learning from the new conditions tested. Simulated results are compared against experimental data to improve the accuracy of the GEM (Kim *et al.*, 2012). The final GEM is released in the standardized SBML format (Systems Biology Markup Language format) (Hucka *et al.*, 2003).

GEMs have countless applications, among them, metabolic engineering, hypothesis-driven discovery, studying multi-species relationships, network property discovery or exploring omics data (Oberhardt *et al.*, 2009). In particular, fungal GEMs have been mainly used for exploring omics data and *in silico* strain engineering (Brandl and Andersen, 2015) Fig 1.

In the following sections, we review metabolic modeling reconstruction, analysis and future perspectives. We present an overview of the process to reconstruct a network with special attention for manual curation. We describe different methods to analyze a model and the integration of omics data in the analysis. We show how GEMs have been applied successfully to predict the behavior of different yeast and filamentous fungi. Finally, we discuss advances to construct GEMs for all sequenced genomes in an automatic manner at a faster rate and improving the quality.

Reconstruction of a Genome-Scale Network

The goal of the genome-scale network reconstruction (GENRE) is to include all the enzymes encoded in the genome (Ruppin *et al.*, 2010). GENREs are built up in a bottom-up manner starting with the annotation data of the genes and the associated enzymatic reactions (Cottret *et al.*, 2018). Gene-protein-reaction (GPR) associations determine the set of metabolic reactions encoded in the genome.

In the past, metabolic networks were step-by-step defined based on the reactions identified *in vitro* (Kornberg and Madsen, 1958) (Elzainy *et al.*, 1973; Kunitake, 1957). Cellular metabolism is more complex and flexible than we often assume (Klein *et al.*, 2017; Koivistoinen *et al.*, 2012; Mojzita *et al.*, 2012). The current methodology used to generate a reliable metabolic network starts with an automatically generated draft based on the sequence similarities between gene annotation and metabolic databases, followed by an extensive manual curation of reactions and GPR mapping done by experts (Hartleb *et al.*, 2018). The process repeats itself until biomass production is achieved. Network reconstruction is a dynamic process in which the experts learn from the simulations and inconsistencies often result in changes in the networks and regular updates. For example, this is illustrated by the publication in 2019 of Yeast8 (Lu *et al.*, 2019), an improved version of the original *S. cerevisiae* metabolic network published in 2003 (Förster *et al.*, 2003b).

Fig. 1 Overview of network reconstruction process and uses of fungal GEMs.

To expedite the GENRE generation process, automatic and semi-automatic algorithms have been developed. In-depth analysis and comparison of current software programs can be found at (Faria *et al.*, 2018; Mendoza *et al.*, 2019). Although the available tools use different algorithms to reconstruct a network, the process follows a similar design: draft reconstruction, manual curation and biomass production. Nevertheless, additional data might be required and the order of the steps described below could be altered (for a more comprehensive explanation on network reconstruction refer to (Thiele and Palsson, 2010), steps 1–37).

Automated Draft Reconstruction

A draft version of the network is constructed based on similarity searches between the sequences found in the genome annotation and metabolic databases. The genome annotation is the keystone to build GPR associations and it defines the gene properties in which the draft reconstruction and curation relies. Even though reannotation of associated genes might occur during the reconstruction of the network, the quality of the annotation should be considered beforehand and, if necessary, improved accordingly (Chain *et al.*, 2009). McDonnell *et al.* (2018) described the step-by-step methodology followed for the curation of the *A. niger* NRRL 3 genome, the only manually curated fungal genome (Vesth *et al.*, 2018).

Algorithms use genome annotation key words like gene ontology (GO) categories (Ashburner *et al.*, 2000; The Gene Ontology Consortium, 2019) or enzyme commission (EC) numbers (NC-IUBMB and webb, 1992) and the information in metabolic databases, automatically annotated and/or manually curated, such as KEGG (Ogata *et al.*, 1999), BioCYC (Karp *et al.*, 2019) or BRENDA (Schomburg *et al.*, 2002) (for an extended list referred to (Blazeck and Alper, 2010)) to associate enzymes and metabolic reactions. Published models can also be used as source of reactions (Aite *et al.*, 2018; Henry *et al.*, 2010; Machado *et al.*, 2018; Olivier, 2018; Wang *et al.*, 2018). The metabolic reactions in the GENRE are described using metabolites and stoichiometry information provided from databases. The first draft generated automatically based on sequence similarity may include a high fraction of inaccurate reactions and GPR associations. In spite of the latest developments, manual curation of the draft is needed to obtain a more accurate network.

Manual Curation of the Draft

In order to easily and efficiently assess the large amount of information included in the draft reconstruction, curators use a confidence score system. This confidence score can be quantitative or qualitative. The minimum information included

should indicate at least if there is no available evidence, evidence for gene function (gene annotation), indirect evidence for biochemical reaction (presence of metabolites, transporters), direct and indirect evidence for gene function (knockout or overexpression experiments) or direct evidence for enzyme function and biochemical reaction (protein structure solved experimentally, biochemical assays) and a reference to the source.

According to the software used to generate the draft, different automatic rules apply to decide if an instance (either reaction or GPR association) should be included into a draft. Independent of the criteria used by each software to add a particular element, curators must decide for each instance whether to keep it or not based on literature, comparative analysis and available experimental data. If an instance is kept, support information and a score need to be added accordingly (Samal *et al.*, 2017). The downside of this method is that only known reactions are identified and species-specific reactions which are not in the databases will not be included. However, the bright side is that reactions already identified on related species are included.

The curation process starts by deciding if a pathway and its reactions are likely to be present in the metabolic network and agree with the organism under study. For example, *A. niger* and *A. nidulans* (Khosravi *et al.*, 2015), shared the D-galactose oxidoreductive pathway with the exception of one reaction for which a gene can be assigned in both species. As a result, the algorithm adds both pathways to the network. Based on literature and experimental data the curator should remove the pathway not supported by the data while adding the information to the correct pathway. In addition, for each reaction, substrates, cofactors, stoichiometry, directionality, localization and enzyme activators and inhibitors as well as the identifiers need to be confirmed and assigned a confidence score. Metabolite identifiers can be obtained from different databases such as ChEBI (Hastings *et al.*, 2013), KEGG (Ogata *et al.*, 1999), PubChem (Kim *et al.*, 2018) or database-independent identifier such as SMILES (Weininger, 1988) or InCHI identifiers (Heller *et al.*, 2013). Known spontaneous reaction should be added only if there is at least one metabolite connecting them to the network.

Once a reaction has been validated, predicted GPR associations need to be confirmed. Unfortunately, due to the lack of experimental data, after curation most of the GPR associations are based on sequence similarity or motif databases such as InterPro (Mitchell *et al.*, 2018) or PFAM (El-Gebali *et al.*, 2018) (included in the gene annotation) and/or to characterized proteins in other species. Eventually, expression and proteomic data can improve the annotation. Other problem that curators face when assigning GPR associations is assigning protein complex (multiple genes – one protein), isozymes (multiple proteins – one function) and promiscuous enzymes (one protein – multiple functions) (Machado *et al.*, 2016), as well as localization of each gene. In addition, in fungi, one of the biggest challenges when assigning GPR associations is defining transporters. Experimental characterization of transporters is a big challenge (Diderich *et al.*, 1999; Forment *et al.*, 2006; Forment *et al.*, 2014; Jørgensen *et al.*, 2007; Kruckeberg *et al.*, 1999; Sloothak *et al.*, 2015) and *in silico* analysis have shown the complexity of the transport systems (Peng *et al.*, 2018; Sloothak *et al.*, 2015).

Once GPR associations have been curated and pathways have been set up, the gaps in the network can be identified. A gap is a missing connection between two metabolites, either the reaction or the enzyme catalyzing the reaction is unknown, and usually it prevents the formation of biomass or known metabolic capabilities in the metabolic reconstruction such as secretion of known metabolic products. An algorithm that automatically include reactions to fill these gaps is called a gap-filling algorithm, and very often, reconstruction tools include gap-filling algorithms as part of their pipeline but not all of them. Pan and Read (2018) described and compared the latest gap-filling algorithms. Different strategies such as revising genome annotation, expression data, database information and comparative genomics are used as input data for gap-filling algorithms. These approaches were used during the generation of genome-scale metabolic network for *A. oryzae* (Vongsangnak *et al.*, 2008), *A. nidulans* (David *et al.*, 2008), *A. niger* (Andersen *et al.*, 2008; Brandl *et al.*, 2018; Lu *et al.*, 2017), *Trichoderma reesei* (Castillo *et al.*, 2016) and *Penicillium chrysogenum* (Agren *et al.*, 2013).

Biomass Formation and Energy Requirements

The final reaction in the metabolic network is the biomass reaction, a generic term for growth. This reaction is not connected to an enzyme and is the sum of many biochemical reactions needed to synthesize known biomass constituents (protein, RNA, DNA, lipids and carbohydrates) and their contribution to the overall cellular biomass. Therefore, the reaction is tailor made for each organism (Agren *et al.*, 2013; Andersen *et al.*, 2008; Castillo *et al.*, 2016). Different methods based on experimental data and omics data have been generated to calculate the biomass composition (Chan *et al.*, 2017; Gonzalez *et al.*, 2010; Santos and Rocha, 2016).

An additional element needs to be added to the biomass reaction to consider growth associated maintenance: energy drain in the form of ATP. ATP acts as a cofactor in many reactions in which stoichiometric coefficients are known. However, ATP is also required during the assembly of polymers or maintenance of gradients, processes resulting in growth (growth associated maintenance), as well as non-growth associated maintenance, which is the ATP required to stay alive. In both cases, stoichiometric coefficients are unknown. Besides, stoichiometry of ATP production through oxidative phosphorylation also needs to be determined (Baart and Martens, 2012). Unknown ATP data can be determined experimentally as described by Van Gulik (2010).

Nutrients are needed to grow a microorganism *in vivo*. In a metabolic model the nutrients are defined by the metabolites encoded in the media formulation and their maximum or minimum uptake are represented with constraints on the metabolic network. The *in silico* media composition determines the metabolites that can be transported inside the cell and those that need to be produced by the network. Changes in the media composition affect biomass reaction and therefore the expected biomass yield. The media composition is important when modeling, especially when studying gene deletion. If a metabolite is required for growth but the enzyme catalyzing the reaction is not present, no growth would be predicted unless the metabolite is supplied in the media. Therefore we can conclude that the gene encoding the enzyme is essential for the network. However, if biomass production is positive, we could predict several scenarios such as a metabolite is not essential for growth, it can be

produced by an alternative pathway or there is more than one enzyme associated to the reaction. For engineered strains, whether is activating or increasing the yield of a pathway, introducing a new pathway from a different species, flux-balance, accumulation of secondary metabolites and/or production of alternative products can be predicted as well (Brandl *et al.*, 2018; Castillo *et al.*, 2016; Pitkänen *et al.*, 2014).

Approaches to Analyze Genome-Scale Metabolic Reconstructions

The process of metabolic refinement ends, according to the protocol for generating high-quality genome-scale metabolic reconstructions (Thiele and Palsson, 2010), with a network able to generate biomass. This reconstruction can be transformed into a GEM, *i.e.*, a mathematical structure in the form of a stoichiometric matrix S , where each row represents a metabolite, columns, metabolic reactions and entries of which represent stoichiometric coefficients. A common approach to model a GEM is Flux Balance Analysis (FBA) (Orth *et al.*, 2010). FBA is a mathematical formulation that allows one to find flux distributions while maximizing an objective function and satisfying mass balance constraints. In mathematical terms,

$$\begin{aligned} & \text{Max } Z \\ & \text{Subject to } S \times v = 0 \\ & v_l \leq v_i \leq v_u \forall i = 1 \dots n \end{aligned} \quad (1)$$

where Z is the objective function, very often the biomass reaction, which represents the specific growth rate [h^{-1}] if the flux values v_i represent specific fluxes, in [$\text{mmol h}^{-1} \text{gDW}^{-1}$]; v_i is the flux through reaction i , v_l and v_u are the lower and upper bounds for that reaction, respectively, n is the number of reactions of the reconstruction and S is the stoichiometric matrix. FBA returns the maximal value of Z , which is unique, and a corresponding set of fluxes through the network. The latter may not be unique (see later).

Generally, immediately after the reconstruction, FBA can be used to test the accuracy of the GEM predictions. Some widely used strategies to validate a GEM include

- (1) Single gene deletion analysis: each gene of the network is knocked-out, reactions depending on the gene are removed from the network and growth is predicted. This obviously requires a set of deletion strains to compare the predictions against – such as for *S. cerevisiae*.
- (2) Qualitative prediction of growth on different carbon sources or media conditions.

In both cases, predictions are compared with experimental data and accuracy scores are calculated:

Sensitivity	$TP/(TP + FN)$
Specificity	$TN/(TN + FP)$
Precision (PPV)	$TP/(TP + FP)$
Negative predicted value (NPV)	$TN/(TN + FN)$
Accuracy	$(TP + TN)/(TP + TN + FP + FN)$
F-score	$2(\text{precision} \times \text{sensitivity})/(\text{precision} + \text{sensitivity})$

In addition, a quantitative prediction of growth on different carbon sources or media conditions can be performed. In this case, specific growth rates are calculated on different scenarios and compared with experimental values. These types of analyses provide insight into the metabolic potential of the organism.

Other Commonly Used Approaches to Study GEMs

Dynamic flux balance analysis (dFBA)

dFBA (Mahadevan *et al.*, 2002; Varma and Palsson, 1994) is an extension of FBA and it calculates metabolite concentrations in time, so batch or feed-batch cultures can be simulated. There are two approaches for dFBA: Static Optimization Approach (SOA) (Varma and Palsson, 1994) and Dynamic Optimization Approach (DOA) (Mahadevan *et al.*, 2002). The first approach, which is implemented in the COBRA toolbox, involves the definition of time intervals and solving instantaneous linear problems at the beginning of each interval, followed by the integration over the interval. In contrast, the second approach involves optimization over the entire time period, solving just once a non-linear problem. The main advantage of the first approach is that it scales well with size as it only involves linear problems, while the advantage of the second approach is that it provides increased flexibility in the definition of constraints and objective function. For example, DOA allows the formulation of a dynamic objective function.

Flux variability analysis (FVA)

In this analysis (Gudmundsson and Thiele, 2010; Mahadevan and Schilling, 2003), each reaction of the network is maximized and then minimized while keeping the specific growth rate at optimal value. A span is calculated for each reaction such that modelers are given the feasible space for each solution, for example to study the uniqueness of an optimal FBA-based flux distribution. FVA

is also useful when the network is constrained with flux data collected during experiments and the corresponding feasible flux space is computed with FVA (Wiback *et al.*, 2004) (this is genome-scale variant of metabolic flux analysis).

Reduced cost analysis

It is often useful to identify which reaction rate constraints limit the objective function. Reduced costs are sensitivity coefficients that indicates how much the objective function would change if the flux through a particular reaction is allowed to change (Palsson, 2015). Thus, these coefficients reflect how the objective function is affected by each reaction bound. Reduced costs can be scaled to the actual flux through the reaction, to not only account for stoichiometry but also the importance (in terms of flux) of a particular reaction (Teusink *et al.*, 2006).

Integration of transcriptomics

Integration of transcriptomics data into GEMs has been widely applied since 2004 (Åkesson *et al.*, 2004). The simplest way it can be achieved, is by assuming that if a particular gene is not expressed, then all the reactions that depend on that gene will not carry any flux. By integrating transcriptomics data into a GEM, a condition-specific (or generally best known as context-specific) subnetwork can be obtained. Simulations ran in this context-specific subnetwork will result in improved predictions when compared with a generic model (Åkesson *et al.*, 2004), mainly because the space of solutions becomes smaller and therefore, more specific and realistic. Several (more sophisticated) algorithms have been reviewed and tested in the past years to integrate transcriptomic data (Machado and Herrgard, 2014; Opdam *et al.*, 2017). However, in many occasions, algorithms are highly dependent on user-defined parameters (Opdam *et al.*, 2017; Richelle *et al.*, 2019a) and additional steps should be done prior to the algorithms application to obtain a better performance (Richelle *et al.*, 2019b).

Integration of proteomics

Since in general, mRNA expression levels cannot be directly correlated with protein concentrations (Lahtvee *et al.*, 2017), proteomics measurements are a more reliable source of information than transcriptomics. Different approaches to integrate proteomics measurements into GEMs have been developed. On a first approach, GEMs can be extended to also account for macromolecular gene expression, also known as Metabolism and Expression (ME) models (Lerman *et al.*, 2012; Thiele *et al.*, 2012). In these models, the mechanism of macromolecular formation is explicitly modeled and proteomic data can be easily integrated (Yang *et al.*, 2016). However, the use of ME models has been challenging because of the lack of specific software but also because they combine linear and non-linear optimization and the simulation time considerably increases (Yang *et al.*, 2018). A different approach is Enzyme-constrained models (Sanchez *et al.*, 2017). In this second approach, each reaction is constrained based on the assumption that it cannot carry more flux than V_{max} . In mathematical terms

$$v_i < V_{max} = k_{cat}[E] \quad (2)$$

In addition, from proteomic data, the total amount of protein can be obtained. Another constraint can be formulated such that the sum of all protein abundances has to be no greater than the total amount of protein in the cell. Thus:

$$\sum_i^n [E_i] < C, \text{ with } n: \text{The number of enzymes, and } C: \text{the total amount to protein}$$

These additional constraints have two advantages: (i) they allow for more realistic behavior of the models, such as overflow metabolism, and the corresponding identification of trade-offs, and (ii) it renders the flux distribution solutions unique. We believe this is the way forward in the field, but it does require estimates of catalytic rates.

Integration of metabolomics

Although we model metabolic networks with GEMs, integration of metabolomics data is not straightforward. The most basic use of metabolomics data is incorporating uptake and secretion rates from exometabolomics. Metabolite concentrations of sugars and metabolic products are measures in chemostats in the feed and waste. Differences in metabolite concentrations can be converted to specific rates and incorporated into genome-scale models as constraints (Mo *et al.*, 2009). More advanced methods also allow incorporation of intracellular metabolite concentrations as constraints on directionality of reactions, using thermodynamic arguments (Fleming and Thiele, 2011; Salvy *et al.*, 2019), or as input to simulate metabolite concentrations over time at genome-scale (Bordbar *et al.*, 2017; Kleessen *et al.*, 2015; Willemsen *et al.*, 2015).

Multi-omics integration

Integration of different kind of metabolic data has resulted in novel metabolic insights such as discovery of mechanisms underlying protein translation or metabolic rewiring of disease states (Cho *et al.*, 2019; Ebrahim *et al.*, 2016), yet algorithms that integrate more than one omics are scarce. Recently, algorithms called TREM-Flux (Kleessen *et al.*, 2015) and REMI (Pandey *et al.*, 2019) have been developed to integrate transcriptomics and metabolomics data into genome-scale models, resulting in enhanced predictions of metabolic fluxes in comparison with the integration of just one type of data.

Metabolic engineering

GEMs can be used to explore modifications leading to higher production rates of certain compounds of industrial interest. For that purpose, several algorithms have been developed (Castillo *et al.*, 2019; Landon *et al.*, 2019; Maranas and Zomorodi, 2016). In the simplest case, knock-out combinations are explored to redirect flux from a by-product to another (Burgard *et al.*, 2003; Patil *et al.*, 2005). In more sophisticated approaches, amplification targets can be detected (Choi *et al.*, 2010) or foreign reactions can be incorporated into the metabolic networks (Pharkya *et al.*, 2004) or knock-outs could also be combined with downregulations (decreased fluxes) and upregulations (increased fluxes) to generate strategies to create improved strains (Pharkya and Maranas, 2006; Ranganathan *et al.*, 2010). Recent efforts have been focused on integration of metabolic and regulatory networks to make predictions more accurate (Shen *et al.*, 2019; Xu, 2018).

Applications of Fungal Models

With the release of the genome sequence of *S. cerevisiae* (Cherry *et al.*, 1997; Goffeau *et al.*, 1996), the first genome-scale model of a eukaryote microorganism was built (Förster *et al.*, 2003b). Due to the conserved functions between humans and *S. cerevisiae* (Nielsen, 2019), this yeast has been subject of extensive research and several updates for the reconstruction of *S. cerevisiae* have been performed (Sanchez and Nielsen, 2015). However, GEMs for several other species of yeasts (Lopes and Rocha, 2017) and filamentous fungi (Brandl and Andersen, 2015) have also been reconstructed and they have been successfully applied in several biotechnological areas. Overall, yeasts and fungal models have been widely applied in predictions of phenotypes and to guide metabolic engineering (Castillo *et al.*, 2019; Nielsen, 2019).

Prediction of Phenotypes

GEMs have been able to accurately predict different types of experimental data. The first applications of these models were to predict, using FBA, flux distributions, growth rates, uptake rates of nutrients or secretion rates of products under different conditions. For example, the first GEM of *S. cerevisiae* (Förster *et al.*, 2003b), iFF708 was used to predict glucose uptake, production of ethanol, glycerol, succinate and CO₂ in different anaerobic glucose-limited continuous cultures with varying dilution rates (Famili *et al.*, 2003). By constraining the model with the corresponding specific growth rates (equivalent to the dilution rate in each condition), experimental uptake and secretion rates were accurately predicted. However, adding more flux constraints will indeed improve the correspondence of the model to data, but prediction more and more could result in overfitting, something to be aware of. The same model was used to predict cell viability under 599 different single gene deletions (Förster *et al.*, 2003a). This large-scale study showed a remarkable accuracy of 87.8% highlighting the model as a predictive tool useful for large screenings.

Later models have focused on improving the quality of the reconstruction, improving its predictions for gene essentiality and integrating different kind of omics such as transcriptomics, metabolomics, fluxomics, proteomics and lipidomics. For example, metabolomics data has been integrated with a GEM of *S. cerevisiae* to find reactions that are affected by genetic (gene deletions) or environmental (oxygen) perturbations (Mo *et al.*, 2009), which may shed light on affected metabolic processes or pathways. More recently, time-resolved metabolomics has been integrated with dynamic flux balance analysis to study the mechanisms underlying metabolic changes in *S. cerevisiae* (Bordbar *et al.*, 2017; Willemsen *et al.*, 2015). Altogether, these studies allowed to understand cellular adaptation of *S. cerevisiae* to environmental and genetic changes.

In spite of the advances in the predictions made with the model of *S. cerevisiae* in terms of gene essentiality and growth measurements, the Crabtree effect remains a challenge for genome-scale metabolic models to predict. Under aerobic conditions, and above a critical specific growth rate of approximately 0.3 (1/h), the metabolism of *S. cerevisiae* changes from respiration to fermentation, even though this is energetically inefficient. Genome-scale metabolic models only take this yield (stoichiometry) into account, and therefore will always predict respiration as the optimal strategy. It is not well understood why this phenomenon occurs but a protein limitation has been suggested as the main cause. Genome-scale models usually do not consider protein limitations but recently, an extended model that include constraints with regard to protein abundances, also known as enzyme-constrained model, has been developed and was able to accurately predict uptake and secretion rates at dilution rates above 0.3 h⁻¹ (Sanchez *et al.*, 2017), supporting the hypothesis that the Crabtree effect is the result of protein limitation. Other approaches such as integration of thermodynamics have also resulted in enhanced metabolic predictions in different conditions (Niegel *et al.*, 2019) and it was recently shown that any additional constraints on a genome-scale metabolic network can lead to switching behavior; the challenge is to use the right experimental data to identify the relevant constraints (De Groot *et al.*, 2019).

A. niger GEM was first published in 2008 by (Andersen *et al.*, 2008). Using iMA873 model, they were able to predict yields of different products, oxalic acid, citric acid and gluconic acid as well as the glucoamylase enzyme. According to the authors, over-prediction of the model might have been explained by the fact that the model predicted a theoretical maximum of a conversion of 100% of carbon source. The updated model iHL1210 included approximately 300 new genes and 400 reactions (Lu *et al.*, 2017). iHL1210 was used to predict growth under 69 carbon and 30 nitrogen sources. According to the results, the accuracy of the GEM was higher on 57 carbon and 22 nitrogen sources compared to the previous model. The latest *A. niger* model iJB1325 was tested against 471 different conditions including carbon and nitrogen sources and gene deletions. Of the 98 test that failed, 76% were due to an unknown metabolic pathway (Brandl *et al.*, 2018). During the reconstruction of the

original model and updates, different kind of omics and comparative analysis were used to improve the annotation and identification of new pathways. Using comparative genomics and protein database information Brand *et al.* were able to identify the genes that allowed to predict growth on L-histidine as single N-source in combination with D-galactose. Furthermore, *adaE*, a new transporter in the *ada* cluster involved in secondary metabolism (Li *et al.*, 2011), was identified through co-expression analysis of individual pathways (Brandl *et al.*, 2018). Another example of comparative genomics and omics data combined with a metabolic network.

Metabolic Engineering

GEMs of Baker's yeast have been successfully applied to generate strains with improved secretion rates of compounds of industrial interest. For example, a GEM of *S. cerevisiae* was used as a tool to explore different strategies to increase the secretion rate of ethanol (Bro *et al.*, 2006). The model predicted that the flux to glycerol could be redirected to ethanol by expressing the heterologous gene *gapN*, which would indirectly provide the NAD^+ that is usually obtained through the generation of glycerol. This strategy was experimentally validated showing that genome-scale models can be used to produce improved strains. The development of more advanced algorithms for strain design and the refinement of the reconstruction of *S. cerevisiae* have allowed to successfully generate strategies leading to an increased production of several other important compounds, such as 2,3-butanediol (Ng *et al.*, 2012), 3-hydroxypropionic acid (Borodina *et al.*, 2015), amorphadiene (Sun *et al.*, 2014), patchoulol (Gruchattka and Kayser, 2015), sesquiterpene (Asadollahi *et al.*, 2009), succinic acid (Otero *et al.*, 2013), triacetic acid lactone (Cardenas and Da Silva, 2014), tyrosine (Cautha *et al.*, 2013) and vanillin (Brochado *et al.*, 2010).

In spite of the widespread use of the *S. cerevisiae* GEMs, other species of yeast which benefit from a GEM have also been used for metabolic engineering (Castillo *et al.*, 2019; Lopes and Rocha, 2017; Simeonidis and Price, 2015). *Pichia pastoris* has been successfully used as a platform for heterologous protein production (Ahmad *et al.*, 2014). A GEM of *P. pastoris*, PpaMBEL1254 (Sohn *et al.*, 2010), was used to generate hypothesis to increase the production of human superoxide dismutase (hSOD) (Nocon *et al.*, 2014). By generating strains with the proposed genetic modifications, the hSOD yield could be increased 20% in relation with the control strain. Other species of yeasts such as *Candida glabrata* (Chen *et al.*, 2013; Li *et al.*, 2014a,b), *Candida tropicalis* (Mishra *et al.*, 2016), *Aureobasidium pullulans* (Feng *et al.*, 2018), *Scheffersomyces stipitis* (Acevedo *et al.*, 2017), *Yarrowia lipolytica* (Huang *et al.*, 2018; Kim *et al.*, 2019; Mishra *et al.*, 2018) and *Rhodospiridium toruloides* (Castañeda *et al.*, 2019) have also benefit from this *in silico* approach.

Although to a lesser extent than yeasts, filamentous fungi have also benefit from *in silico* metabolic engineering algorithms to find gene targets to overproduce certain compounds. A metabolic network for *A. niger* predicted that deletion of two genes, *pdc* and *acl*, would lead to an increased production of succinic acid (David *et al.*, 2003), which was later experimentally validated (Meijer *et al.*, 2009). Other successful examples of uses of GEMs in metabolic engineering for filamentous fungi can be found for *Ashbya gossypii* (Ledesma-Amaro *et al.*, 2015a,b; Serrano-Amatriain *et al.*, 2016). Although GEMs for several other species of filamentous fungi exist (Agren *et al.*, 2013; Castillo *et al.*, 2016; David *et al.*, 2008; Dreyfuss *et al.*, 2013; Liu *et al.*, 2013; Pitkänen *et al.*, 2014; Samal *et al.*, 2017; Vongsangnak *et al.*, 2008, 2013, 2016; Ye *et al.*, 2015), they have not yet been used for metabolic engineering or their predictions to increase product formation remain to be tested, probably because of delay in the development of efficient tools for genetic manipulation in comparison with *S. cerevisiae*.

Future of Metabolic Modeling of Fungi

The availability of genomes of fungal organisms has increased dramatically due to advances in sequencing technology. Genome sequencing has increased in throughput and decreased in cost, which has enabled the advent of large-scale sequencing projects. The Fungal Genomics Initiative led by the Broad Institute have created a resource of around 50 fungal genomes (Cuomo and Birren, 2010). To broaden the diversity of sequenced fungal genomes, the Joint Genome Institute (JGI) initiated the 1000 fungal genome (1FKG) project and have produced hundreds of fungal reference genomes that cover the entire fungal tree of life (see "Relevant Websites section") (Martin *et al.*, 2011). On completion of the 1FKG project, there will be at least one reference genome for every known family of fungi. The vast genomic resources now available for diverse fungi will provide the basis for more exploration, including in the modeling and analysis of fungal metabolic models (Grigoriev *et al.*, 2014).

High-quality fungal GEMs are limited to model organisms, for which experimental data exists for manual curation. With the recent increase in the number of sequenced fungal genomes, there is a growing demand for new bioinformatics tools for GEM building and analysis. The introduction of new automated tools that facilitate the rapid generation of models has made GEMs much more accessible to the research community studying a range of fungal organisms. One such resource is KBase (see "Relevant Websites section"), which provides a platform for tools to perform metabolic modeling of fungi and integrated data analyses (Arkin *et al.*, 2018). For example, a user can construct a metabolic model from an input genome annotation based on a curated reference set of reactions that are derived from published fungal GEMs. First, orthologous proteins are identified to detect the presence of protein families. Then, reactions are propagated from the reference set based on presence of the protein family in the genome annotation to the metabolic model. The automated output is a draft model that can be further refined

manually based on literature and experimental data or using gap-filling tools also available in KBase. Other automated tools, such as Pathway Tools (Karp *et al.*, 2016), CoReCo (Pitkänen *et al.*, 2014), and RAVEN (Wang *et al.*, 2018), also offer fast generation of fungal GEMs.

Automated modeling enables large-scale analysis of GEMs of fungi within the same framework, which offers the advantage of side-by-side comparisons. These comparisons can help identify global trends in metabolic traits across fungal families (Pitkänen *et al.*, 2014) and contribute to comparative genomics analyses. However, a major challenge for these methods is the lack of accuracy for species that have greater divergence from the current reference species. High-quality GEMs still require manual curation to obtain an accurate representation. Yet, as tools continue to be improved and new ones are developed, the time to obtain informative and predictive models will be substantially decreased, and the availability of fungal GEMs will increase.

With advances in high-throughput experiments, metabolic modeling is benefitting from the integration of experimental data from a variety of genome-scale approaches. Integration of gene regulation has been applied towards metabolic modeling (Osterlund *et al.*, 2013), but improvement is still needed to accurately reflect complex forms of regulation, like post-translational modifications. Recently, bioinformatics methods are using metabolomics datasets to mine reaction databases for predicting new gene annotations and creating better GEMs (Erbilgin *et al.*, 2019). Lastly, the rise of gene editing technologies will facilitate validation and improvement of GEMs through the testing of predictions (Idnurm and Meyer, 2018). The next steps are to apply functional genomics methods more broadly to new organisms to identify the functions of unknown genes. Characterization of new genes and pathways will help us better model biology that has been previously unknown.

Conclusions

GEMs are a valuable tool to understand the intricacies of an organism's metabolism. Despite the large number of sequenced fungal species, their use is not as extensive as in other fields. The high number of species in the kingdom, lack of previous knowledge to improve manual curation, availability of experimental data for validation of the model together with the time and human resources needed to reconstruct a high-quality genome are among the reasons. As new methodologies develop to integrate omics data and comparative genomics while decreasing time and improving the quality, new metabolic models will appear to understand the most challenging and newest species with biotechnological and even medical value.

Introduction

Low molecular weight carboxylic acids are intermediates of the primary metabolism of almost all organisms. Some of them are also commodity (bulk) products and manufactured on a very large scale to satisfy various global markets. In fact, after antibiotics and amino acids, organic acids represent the third largest category of bulk chemicals manufactured by microbial fermentation (Anastassiadis and Morgunov, 2008). Their carboxylic group(s) is/are only partially dissociated in neutral aqueous solutions, which makes them a weak acid, optimal for food applications such as flavors and preservatives. Carboxylic acids can also function as potential bio-based building blocks for polymer production and suitable platform chemicals in green chemistry. Recently, over 300 chemicals that can be produced from biomass and have the potential to be transformed into new type of useful molecules were analyzed by the U.S. Department of Energy to select the most lucrative ones. Of the top twelve such compounds, eight are organic acids, underlining the importance of this group (Werpy and Petersen, 2004). However, to successfully compete with petroleum-based chemical technologies, economic efficiency of the bio-based organic acid production processes must improve.

Why Do Fungi Accumulate Organic Acids?

The reasons why fungi have developed the ability to accumulate and excrete organic acids in high amounts is not sufficiently understood. In contrast to other fungal biotechnological products such as secondary metabolites or enzymes, prolific organic acid accumulation is not restricted to carefully selected mutants, but even wild-type strains can do it under special cultivation conditions. These are: a high concentration ($> 10\%$, $w v^{-1}$) of a rapidly metabolizable carbon source (usually D-glucose), a high rate of aeration, and a suboptimal concentration of nitrogen and phosphorus to limit biomass formation (= growth). Obviously, these are conditions a fungus rarely encounters in its natural habitat, where it mostly feeds on polysaccharides and proteins. It has been discussed that the purpose of the extracellular accumulation of organic acids is to decrease the pH of the environment in cases of presence of excessive amounts of a carbon source in order to prevent its utilization by other competing micro-organisms (such as bacteria and yeasts), and at the same time transform the carbon source to one that is difficult for them to utilize (Blatzer and Latgé, 2017). Organic acid formation has also been interpreted as a mechanism to chelate trace metal ions, thereby facilitating their transport into the cell, but while they may indeed play such a role in at least some cases (Guerinot *et al.*, 1990; Odoni *et al.*, 2017b), this would clearly not necessitate their accumulation in such high amounts.

Biochemical Aspects of Organic Acid Accumulation by Fungi

The organic acids accumulated by fungi can be distinguished into four types: (a) monocarboxylic acids; (b) dicarboxylic acids; (c) tricarboxylic acids; and (d) sugar acids. As illustrated in Fig. 1, lactic acid is the only monocarboxylic acid produced by some fungi in significant amounts that is a definitive end-product of glycolysis. Gluconic acid biosynthesis is an extracellular process and its uptake competes with glucose transport. The di- and tricarboxylic acids, however, can be considered as products of incomplete aerobic D-glucose catabolism. This incomplete catabolism (a–c) has been coined by Foster (1949) as “overflow metabolism”, because it is best observed in the presence of high concentrations of D-glucose. One may argue that fungi – usually feeding on polymers – are not well equipped with regulatory mechanisms to handle the metabolism of high monosaccharide concentrations. However, the analysis of metabolic control points in fungi has documented that they operate in a similar way as in other organisms. Rather certain nutritional imbalances (low nitrogen and phosphate, limitations in inorganic ions) are responsible for the overflow metabolism (Kubicek and Röhr, 1985).

Fungi are unique in other metabolic properties though: they possess a pyruvate carboxylase that is located in the cytosol (Osmani and Scrutton, 1985; Bercovitz *et al.*, 1990; Jaklitsch *et al.*, 1991), and which can utilize the glycolytically formed pyruvate to form oxaloacetate. In addition, there are cytosolically located isoenzymes of NAD-dependent malate dehydrogenase and (in Mucorales) fumarate hydratase, which together form a “reductive tricarboxylic acid (rTCA) branch” (Fig. 1). Since the pathway consumes 1 ATP per pyruvate (in the pyruvate carboxylase reaction) and oxidizes the NADH formed during glycolysis, one may consider it a non-energy generating pathway for D-glucose catabolism. Three of the dicarboxylic acids overproduced by fungi (oxalic acid, malic acid, fumaric acid) are intermediates of the rTCA branch. However, succinic acid and trans-epoxysuccinic acid – although only one and two enzymatic steps, respectively, away from fumarate – are not produced by the rTCA branch because the

Fig. 1 Simplified biochemical pathways for organic acid synthesis in fungi. Each number indicates an enzymatic reaction catalyzed by the following enzymes: (1) glucose oxidase, (2) gluconolactonase, (3) citrate permease, (4) itaconate permease, (5) hexose permease, (6) monocarboxylic acid permease, (7) dicarboxylic acid permease, (8) pyruvate carboxylase, (9) cytosolic NAD-specific malate dehydrogenase, (10) cytosolic fumarase, (11) lactate dehydrogenase, (12) oxaloacetate hydrolase, (13) *cis*-aconitate decarboxylase, (14) mitochondrial malate/*cis*-aconitate antiport, (15) mitochondrial malate dehydrogenase, (16) citrate synthase, (17) aconitase, (18) pyruvate dehydrogenase complex, (19) mitochondrial citrate/malate antiport.

enzyme catalysing the conversion of fumarate to succinate – fumarate reductase – has not been detected in filamentous fungi yet (Yang *et al.*, 2016a). Succinate can therefore be formed only via the TCA cycle.

The major question regarding the operation of the rTCA branch is the origin of the CO₂ used by pyruvate carboxylase. During D-glucose catabolism via glycolysis, no carbon dioxide is released. Catabolic pathways that would generate CO₂ are the pentose phosphate pathway and the TCA cycle. However, in both cases CO₂ production would cost one carbon by pyruvate formed and decrease the yield by a third. Consequently, a high yield of dicarboxylic acid from glucose can only be obtained by adding extra carbon dioxide (either as CaCO₃ or as CO₂). As illustrated below, this principle has indeed been used in the fermentative

production of malate and fumarate. If added in the same molarity as D-glucose, the theoretical yield would then be 2 moles dicarboxylic acid from 1 mol of D-glucose.

The pyruvate carboxylase is also the key for the accumulation of the tricarboxylic acids, because the formation of citrate occurs by the citrate synthase catalyzed condensation of oxaloacetate and acetyl-CoA (Cleland and Johnson, 1954). The latter arises by oxidative decarboxylation and the released CO₂ is used as a substrate for pyruvate carboxylase. Since the biosynthesis of these two acids involves mitochondrial enzymes, export from and import into the mitochondria are another critical steps in their accumulation (Torres, 1994a,b).

The accumulation of the two tricarboxylic acids shares two additional peculiarities that are absent from the mono- and dicarboxylic acids: first, the stoichiometry of citrate (end-product of citric acid and intermediate in itaconic acid production) formation from D-glucose is the following:

The equation indicates that every mole of hexose needs an additional half mole of oxygen to get converted to citric acid. This 2 to 1 ratio is remarkable because oxygen is about 40–60,000 times less soluble in water than D-glucose (under normal conditions, the oxygen solubility is $2.56 \times 10^{-4} \text{ mol L}^{-1}$, i.e., $\sim 8 \text{ mg L}^{-1}$), and emphasizes the critical role that dissolved oxygen (and its continuous, high-rate replenishment) plays in citric and itaconic acid fermentation. It further implies that the fungus must contain a powerful system to reoxidize the NADH formed in glycolysis without ATP formation. Since fungal growth is practically at a standstill in the acid production stage, no biosynthetic demand for ATP exists, and thus high-rate carbon catabolism would result in high energy charge (= increased ATP levels). ATP is mostly generated during mitochondrial terminal oxidation, and would allosterically inhibit the glycolytic pathway. However, the electron transport chain of fungal mitochondria contains another terminal oxidase, the cyanide-resistant alternative oxidase (AOX) that uncouples mitochondrial NADH regeneration and ATP synthesis, allowing carbon catabolism and subsequent citric and itaconic acid formation to proceed unabated (Fig. 2). Indeed, alternative oxidase has been shown to play a crucial role in the production of both tricarboxylic acids (Kubicek *et al.*, 1980; Molnár *et al.*, 2018). This enzyme is resistant to the inhibitors of the cytochrome oxidase such as cyanide or azide and sensitive to salicylhydroxamic acid. Most importantly, alternative respiration is associated with proton translocation only at Complex I, whereas the other proton-pumping sites are bypassed. Activation of the alternative oxidase therefore significantly reduces ATP generation and, in effect, ATP inhibition over carbon catabolism (Kirimura *et al.*, 2000). However, some of the ATP generated via the standard respiratory chain will still be needed for maintaining pH homeostasis, because of the formation of 4 protons per mole glucose consumed.

Secondly, both tricarboxylic acid fermentations are extremely sensitive to the presence of trace quantities of Mn²⁺ ions, which usually have to be $< 10^{-7} \text{ M}$ (Kisser *et al.*, 1980). The reason for this requirement is still not sufficiently understood. One aspect could be the fact that these limiting concentrations of Mn²⁺ ions induce a very compact morphology and small pellet size that strongly improves mass and oxygen transfer (Papagianni and Mattey, 2006; Karaffa *et al.*, 2015; Sun *et al.*, 2018). This hypothesis has, however, not yet been tested in reverse. In *Aspergillus terreus*, manganese deficiency has also been shown to trigger the expression of the alternative oxidase (vide supra). This could be due to an impairment of superoxide dismutase (a manganese-requiring enzyme), which would increase the oxidative stress, a condition known to induce alternative oxidase (Molnár *et al.*, 2018). However, this hypothesis still requires experimental verification. A deficiency in Mn²⁺ ions has also been demonstrated to lead to changes in metabolite concentrations that favor the activities of two of the regulatory steps in glycolysis (6-phosphofructokinase and 6-phosphofructo-2-kinase, which are inhibited by citrate and itaconate), but clear evidence is also lacking (Habison *et al.*, 1983; Arts *et al.*, 1987; Tevž *et al.*, 2010; Huang *et al.*, 2014). The requirement for a fermentation medium with only extremely low

Fig. 2 Schematic overview of the mitochondrial respiratory pathways including the cyanide-resistant alternative oxidase (AOX).

concentrations of Mn^{2+} ions looks like an obstacle for production of these two acids. However, its removal by precipitation (with hexacyanoferrate), antagonization (with copper ions or lower alcohols) or addition of compounds affecting membrane permeability (quaternary ammonium salts) is well-practiced standard for over 50 years (for review see Kubicek and Karaffa, 2010). Alternatively, the recent identification of the manganese transporter of *A. niger* (DmtA), whose knock-out results in Mn^{2+} -insensitive production of citric acid (Fejes *et al.*, 2020), offers new strategies to solve this problem.

Description of the Production of Organic Acid

Below we describe the details and state of the art of the biochemistry and production of the most important fungal organic acids.

Monocarboxylic Acids

L-lactic acid

Lactic acid is a colorless, odorless monocarboxylic acid that is broadly used as an excipient in the food, cosmetics, pharmaceutical, and chemical industries (Vijayakumar *et al.*, 2008; Miller *et al.*, 2011). The L-form also serves as a building block for poly-lactic acid (PLA), a biodegradable polymer that could be set to replace petroleum-based plastics. Industrially, lactic acid can be manufactured by either through chemical synthesis or by microbial fermentation. Nowadays, the latter heavily dominates (80%–90%; Endres and Siebert-Raths, 2009). Lactic acid production traditionally uses lactic acid bacteria (*Lactobacillus* spp.) with yields approaching the theoretical maximum of 100% (w w^{-1}) of homolactic fermentation (= production of two moles of lactate from one mole of glucose, as opposed to heterolactic fermentation that produces one mole of lactate from one mole of glucose, as well as carbon dioxide and acetic acid/ethanol). A disadvantage of this process is the requirement for complex nutrients and the need to keep the $\text{pH} > 6$ during fermentation (Hofvendahl and Hahn-Hägerdal, 2000). Therefore, lactic acid production processes have been developed with yeasts of the genera *Saccharomyces* (Colombié *et al.*, 2003; Skory, 2003b; Ishida *et al.*, 2005; Saitoh *et al.*, 2005; Valli *et al.*, 2006), *Kluyveromyces* (Bianchi *et al.*, 2001), and *Candida* expressing heterologous lactate dehydrogenase (*ldh*) genes (Osawa *et al.*, 2009; Ilmén *et al.*, 2013; Koivuranta *et al.*, 2014). This yeast-based strategy has reached industrial application and allows lactic acid production on pretreated corn starch, sugarcane or sugar beet (Miller *et al.*, 2011).

Filamentous fungi would offer the possibility of using lignocellulosic carbohydrates for production of lactic acid. Until today the only fungus known to accumulate large concentrations of lactic acid is *Rhizopus oryzae*, whose ability has been demonstrated already more than 100 years ago (Saito, 1911). Production from low-cost carbon sources such as raw starch, wheat straw, and cellulose has been reported (Tay and Yang, 2002; Park *et al.*, 2004; Vially *et al.*, 2010). Already Ward *et al.* (1938) described a fermentation process utilizing *R. oryzae*, which resulted in 63%–69% yields of L-lactic acid from chemically defined media containing 15% (w v^{-1}) glucose. The fermentation with *R. oryzae* offers several advantages over the bacterial or yeast processes: (a) a chemically defined medium with inorganic nitrogen sources can be used which simplifies product purification; (b) the fungus can metabolize high concentrations of glucose, resulting in high product concentrations; (c) enantiomerically pure L-lactic acid, necessary for food applications and preferred for PLA (poly-lactic acid, or polylactide) manufacturing can be produced. The disadvantage of *R. oryzae* is the requirement of a near-neutral pH, which – as in the *Lactobacilli* (vide supra) – compromises cost efficacy, and the by-production of ethanol, L-malic acid and fumarate (Soccol *et al.*, 1994; Magnuson and Lasure, 2004; Zhang *et al.*, 2007; Mudaliyar and Kulkarni, 2012).

The maximal theoretical yield for lactic acid production by aerobic respiration is 2 moles per mole of D-glucose, which equals a yield (g g^{-1}) of 1.0. Highest reported yields so far were 0.88 g g^{-1} (Zhou *et al.*, 1999). However, as noted above, L-lactic acid production in *R. oryzae* is accompanied by the formation of ethanol and malic acid (Meussen *et al.*, 2012). The accumulation of these by-products implies that there is a competition between lactate dehydrogenase, pyruvate carboxylase, and pyruvate decarboxylase for pyruvate, their common substrate. This has recently been quantified by determining the respective control coefficients for these enzymes (Ke *et al.*, 2015). The obligatory addition of calcium carbonate for pH maintenance helps to decrease ethanol formation, but the carbonate anion is used by the pyruvate carboxylase for oxaloacetate (and subsequent malic and fumaric acid) formation. Varying the carbonate concentrations from 0 to 30 mM showed that ethanol did not reach a minimum before fumarate and malate had begun to increase, indicating that minimizing the formation of these side products would not be possible through adjustment of carbonate concentrations alone (Longacre *et al.*, 1997). The authors therefore isolated mutants with decreased ethanol production to enable *R. oryzae* to grow anaerobically in the production phase, which eliminates metabolic flux to malate, and one such a mutant indeed reached an 86% (g g^{-1}) yield of lactic acid production. Thitprasert *et al.* (2011) added the alcohol dehydrogenase inhibitor 2,2,2-trifluoroethanol to cultures of *R. oryzae* and obtained a higher yield of lactic acid. Skory *et al.* (1998) isolated mutants with strongly decreased alcohol dehydrogenase activity levels, but found that they still produced substantial amounts of ethanol under anaerobic conditions. Consequently, the strategy of choice must be the inhibition of the pyruvate decarboxylase. However, despite of the cloning of the genes encoding the two pyruvate decarboxylases (Skory, 2003a), no attempts to knock them out have so far been reported. In contrast, Thitprasert *et al.* (2014) used 4-methylpyrazole, glyoxylic acid, and 3-hydroxypyruvate addition to inhibit pyruvate decarboxylase activity. Indeed, 0.1 mM 4-methylpyrazole and $1.0 \mu\text{M}$ 3-hydroxypyruvate effectively hampered ethanol production. However, because of the very broad specificity of these compounds, the activity of lactate dehydrogenase was also affected which rendered this approach not feasible.

The biochemistry of lactate synthesis by *R. oryzae* is well understood: *R. oryzae* contains three L-lactate dehydrogenases (LDH), including two NAD-dependent LDH isozymes (LdhA and LdhB; Pritchard, 1971; Yu and Hang, 1991; Skory, 2000, 2001) and a mitochondrial NAD-independent LDH (Pritchard, 1971). Notably, no D-lactate dehydrogenases are present in *R. oryzae*. The equilibrium of LdhA lies strongly on the side of lactate, whereas the equilibrium of LdhB is toward pyruvate (Skory, 2000). The results of transcriptional and enzyme activity analyses show that *ldhA* is responsible for most of the lactic acid produced by this fungus (Skory, 2000; Saito *et al.*, 2004). More recently, researchers have therefore investigated the possibility of producing L-lactic acid with *Aspergillus* spp., which can grow and produce organic acids at low pH. The drawback is that most *Aspergillus* genomes do not contain *ldh* genes, and in those who have one (e.g., *A. oryzae*) it interferes with lactic acid formation (Wakai *et al.*, 2014). The strains tested were therefore first transformed with heterologous *ldh* genes. So far, this strategy has been applied in three *Aspergillus* spp. (*A. niger*, *A. oryzae*, and *A. brasiliensis*) with *ldh* genes from different sources (*R. oryzae*, mouse, and cattle; Wakai *et al.*, 2014; Dave and Puneekar, 2015; Liaud *et al.*, 2015). L-Lactic acid production was, however, much lower than in the yeast processes (generally below 50% of the theoretical yield, g g⁻¹).

Dicarboxylic Acids

Oxalic acid

Oxalic acid is probably the most widespread dicarboxylic acid that is produced by fungi, including brown-rots, white-rots, mycorrhizae, plant pathogens, and opportunistic mammalian pathogens (Dutton and Evans, 1996; Cadd, 1999). Because of its ability to strongly chelate Ca²⁺ ions, oxalate is toxic and thus no desired product in biotechnology. In fact, during citric acid production by *A. niger* oxalate can also be formed, and this has been solved by using oxalate non-producing mutants because oxalate accumulation occurs within a broad pH range (pH 2–6; although highest concentrations are observed at pH > 4 Cleland and Johnson, 1956). The reason why so many fungi excrete oxalic acid is probably because it provides an easy means to acidify the medium (Dutton and Evans, 1996). In plant and human pathogenic fungi, oxalate formation has been linked to virulence. It stimulates plant lignocellulose degradation by acidification, which favors pathogen proliferation in the plant and in humans, as the calcium oxalate crystals block vessel or bronchioles (Jordan *et al.*, 1996; Nakagawa *et al.*, 1999; Lane, 2002). In brown-rot fungi – such as *Postia placenta* or *Gloeophyllum trabeum*, which combine Fenton-based oxidation and enzymatic catalysis to degrade wood – oxalate can promote Fenton chemistry by mobilizing Fe³⁺ as mono-oxalate (Presley *et al.*, 2018).

Three potential biosynthetic pathways have been proposed for oxalate formation in fungi: oxidation of glyoxylate (Balmforth and Thomson, 1984), oxidation of glycolaldehyde (Hammel *et al.*, 1994), and hydrolysis of oxaloacetate (Lenz *et al.*, 1976; Kubicek *et al.*, 1988). While the former two possibilities were proposed on the basis of enzyme activity measurements during oxalate formation, scientific proof by ¹⁴C-incorporation studies and gene deletion in *A. niger* provided evidence for the origin of oxalate from D-glucose or other hexoses by hydrolysis of oxaloacetate via oxaloacetate hydrolase (Kubicek *et al.*, 1988; Pedersen *et al.*, 2000), a C(α)–C(β) bond lyase that is a member of the phosphoenolpyruvate mutase/isocitrate lyase enzyme superfamily (Han *et al.*, 2007). This mechanism has since been also confirmed in plant and human ascomycetous pathogens and basidiomycetes (Munir *et al.*, 2001; Joosten *et al.*, 2008; Chen *et al.*, 2010; Gombert *et al.*, 2011; Andrew *et al.*, 2012; Nagy *et al.*, 2012; Liang *et al.*, 2015; Presley *et al.*, 2018). Interestingly, Poulsen *et al.* (2012) identified a transcription factor (OafA) in *A. niger*, whose knock out causes an increase in the expression of the oxaloacetate hydrolase – encoding *oahA* gene at high pH, and leads to enhanced oxalate formation. At the same time, oxidative phosphorylation was down-regulated in the *oafA* mutant, indicating an indirect relationship between the two. This assumption is consistent with the recent demonstration that the overexpression of the *aoxA* (alternative oxidase-encoding) gene in *A. niger* significantly increases the rate of oxalate accumulation (Yoshioka *et al.*, 2019). These two findings are first indications that ATP-non forming NADH reoxidation, in addition to tricarboxylic acids, is also important for the accumulation of dicarboxylic acids.

L-Malic acid

L-Malic acid is produced to satisfy the increasing demand for nutritional bars and protein drinks as well as healthier functional beverages with high nutrient flavors. Yet for economic reasons, majority of the 182.6 million US\$ market (2018) are still produced by chemical means. L-Malic acid production has originally been observed in *Aspergillus* spp. (Abe *et al.*, 1960; Peleg *et al.*, 1988, 1989a; Bercovitz *et al.*, 1990; Battat *et al.*, 1991) and in *R. oryzae* (Longacre *et al.*, 1997). In *Aspergillus* spp., malate can be considered as an end-product of glycolysis and the rTCA branch (*vide supra*). During a screening of nine *Aspergillus* spp., *A. flavus* (strain ATCC 13697) was detected as the best producer of L-malic acid (Bercovitz *et al.*, 1990). After optimization of fermentation parameters and the addition of CaCO₃, L-malate production with yields up to 128 mol percent (95 wt%) were obtained (Battat *et al.*, 1991). However, the use of *A. flavus*, which can also produce aflatoxins, is in conflict with the requirements for the safe production of food grade L-malate. Therefore, a cryptic but not aflatoxin forming species of the *A. flavus* group – *A. oryzae* (Geiser *et al.*, 1998) – was investigated for production of L-malic acid (Knuf *et al.*, 2013). Brown *et al.* (2013) further improved malic acid production from D-glucose and CaCO₃ with *A. oryzae* by overexpression of a native C4-dicarboxylate transporter, and the native cytosolic alleles of pyruvate carboxylase and malate dehydrogenase. A strain overexpressing all three genes accumulated 154 g L⁻¹ L-malate in 164 h, corresponding to a production rate of 0.94 g L⁻¹ h⁻¹. This indicates that in the presence of extra carbon dioxide, the enzymes of the rTCA pathway limit the flux rate. Liu *et al.* (2017) extended this strategy by additional heterologous expression of a phosphoenolpyruvate carboxykinase and phosphoenolpyruvate carboxylase from *Escherichia coli* (both to support the native

pyruvate carboxylase in oxaloacetate formation), and by overexpression of the 6-phosphofructokinase encoding gene *pfkA* which was found to limit the glycolytic flux rate to malate. The final engineered *A. oryzae* strain produced 165 g L^{-1} L-malate with a productivity of $1.38 \text{ g L}^{-1} \text{ h}^{-1}$ in fed-batch culture. Most recently, the strategy of enhancing the rTCA branch was also applied to produce L-malic acid by *A. niger*: to bypass the accumulation of oxalic acid, Xu *et al.* (2019) generated an efficient malate-producing strain by deletion of the oxaloacetate hydrolase gene *oahA* which competes with malate dehydrogenase for oxaloacetate in this fungal species. Subsequent overexpression of the genes encoding pyruvate carboxylase, a cytosolic malate dehydrogenase and the C₄-dicarboxylate transporter gene *c4t318* allowed production of 120.4 g L^{-1} malic acid in shake flasks, and 201.2 g L^{-1} in fed-batch fermentation.

One of the drawbacks of L-malate fermentation is the inevitable byproduction of mitochondrially produced succinate. Liu *et al.* (2018) therefore tested an alternative strategy, i.e., the engineering of the mitochondrial pathway for L-malate production in *A. oryzae*. To minimize pyruvate accumulation, they first constructed a strain that overexpressed a pyruvate carboxylase gene from *R. oryzae* both in the cytosol and mitochondria of *A. oryzae*. This strain was then further engineered by enhancing the expression of the two genes that encode the enzymes of the glyoxalate cycle, i.e., isocitrate lyase and malate synthase. In addition, they lowered the expression of citrate synthase, overexpressed the mitochondrial dicarboxylate carrier Sfc1p from *S. cerevisiae*, and finally overexpressed an NADH oxidase from *Lactococcus lactis* to decrease the NADH/NAD⁺ ratio. This engineered *A. oryzae* strain produced 117.2 g L^{-1} L-malate with a productivity of $1.17 \text{ g L}^{-1} \text{ h}^{-1}$ from 130 g L^{-1} D-glucose and 90 g L^{-1} CaCO₃, while only 3.8 g L^{-1} succinate were formed.

Fumaric acid

Fumaric acid, is broadly used as a food acidulant, in the manufacture of polyester resins and polyhydric alcohols, and as a mordant for dyes. Its esters can be used in medicine to treat relapsing-remitting multiple sclerosis and have immunomodulating activities (Balak *et al.*, 2016). It is currently produced via petrochemical routes by catalytic isomerization of maleic acid in aqueous solutions at low pH (Martin-Dominguez *et al.*, 2018). Alternatively, it can be produced from D-glucose in fermentation by *R. oryzae* (Foster and Waksman, 1939; for review see Sebastian *et al.*, 2019), which later on was found to be a separate species, *R. delemar* (Abe *et al.*, 2007) which lacks the lactate dehydrogenase LdhA and therefore cannot produce lactic acid. The nutritional and physical requirements of *R. delemar* leading to maximum yields of fumarate have been examined, and like other fungal fermentations accumulating high concentrations of organic acids, high carbohydrate concentrations, a high carbon to nitrogen ratio, and addition of CaCO₃ are necessary to achieve high fumaric acid yields (60%–70% of D-glucose; g g^{-1} ; Rhodes *et al.*, 1959). To minimize the potential by-production of ethanol, high oxygen tension is applied (Roa Engel *et al.*, 2008; Straathof and van Gulik, 2012). Proof for the biosynthesis of fumaric acid via the rTCA branch has been reported (Romano *et al.*, 1967; Overman and Romano, 1969; Osmani and Scrutton, 1985; Kenealy *et al.*, 1986; Peleg *et al.*, 1989b): an increase in the activity of the cytosolic pyruvate carboxylase was observed to correlate with glucose utilization and fumarate production in *R. delemar* (Overman and Romano, 1969). To overcome a possible limitation of the flux at this step, Zhang *et al.* (2012) overexpressed the endogenous pyruvate carboxylase (*pyc*) and also introduced the phosphoenolpyruvate carboxylase (*pepC*) gene from *E. coli*. Fumaric acid production by the *pepC* transformant increased by 26% (g g^{-1}), but the *pyc* transformants grew poorly and had low fumaric acid yields ($<0.05 \text{ g g}^{-1}$ glucose). This was probably due to the formation of large pellets that impaired oxygen transfer and consequently resulted in the accumulation of ethanol.

The cytosolic fumarate hydratase (FumR) activity which is present in *Rhizopus* spp. also increases during the production stage of the fumarate fermentation (Peleg *et al.*, 1989b). The role of the latter is, however, still unclear: its overexpression in *R. delemar* and other fungi resulted in the accumulation of more L-malate than fumarate (de Jongh and Nielsen, 2008; Xu *et al.*, 2012; Zhang and Yang, 2012), which is consistent with the fact that the equilibrium of FumR lies on the side of L-malate (Meussen *et al.*, 2012). It is likely that *R. delemar* has a specific fumarate transporter which removes fumarate from this equilibrium, but this has not been investigated so far. Interestingly, a transcriptomic and proteomic analysis has recently led to the hypothesis that during nitrogen starvation a substantial part of accumulated fumarate accumulates from the urea cycle due to amino acid catabolism (Odoni *et al.*, 2017a). The responsible enzyme – argininosuccinate lyase – is located in the cytosol, and the resulting fumarate therefore needs no further transport step to mix with the rTCA fumarate pool. This offers new strategies for the improvement of fumarate production.

Succinic acid

Succinate has been ranked within the top 12 bio-based products by the US Department of Energy (Werpy and Petersen, 2004) and hence there are numerous efforts to produce succinate biotechnologically, using recombinant anaerobic and aerobic bacteria and yeasts (Ahn *et al.*, 2016). For this reason, production by fungi was only scarcely studied. *Aspergillus carbonarius*, a member of black aspergilli was more recently introduced as a producer of L-malic acid (Weyda *et al.*, 2014), because it is known to produce citric, gluconic and malic acid from varieties of carbohydrate containing substrates, and tolerates low pH (Yang *et al.*, 2016a). Since, as outlined above, fungi do not have a cytosolic fumarate reductase, Yang *et al.* (2016b) transformed *A. carbonarius* with the *frd* gene from *Trypanosoma brucei*, which encodes an NADH-dependent fumarate reductase gene. It has been shown to be located in the cytosol and to be rate limiting for succinate accumulation by *T. brucei* (Besteiro *et al.*, 2002). To this end Yang *et al.* (2016b) used a glucose oxidase deficient strain of *A. carbonarius* that overexpressed the native *A. carbonarius* C₄-dicarboxylate transporter as a host. Impacts of the introduced genetic modifications on organic acid production were investigated in a defined medium and in a hydrolysate of wheat straw containing high concentrations of glucose and xylose. They found that overexpression of the C₄-dicarboxylate transporter alone and in combination with the *frd* gene significantly increased the production of C₄-dicarboxylic acids and reduced the

accumulation of citric acid, whereas expression of the *frd* gene alone did not result in any significant change of organic acid production profile. However, despite of the use of 80 g L^{-1} D-glucose and CaCO_3 , respectively, the yields from D-glucose were below 30 g L^{-1} , and besides minor amounts of citric and fumaric acid, the strain produced even higher amounts of L-malic acid than succinic acid. An explanation for this could be that – as explained above – the combination of glycolysis and the rTCA branch of *Aspergillus* spp. produces neither ATP nor NADH, and fumarate reductase therefore faces a shortage of its co-enzyme.

Trans-2,3-epoxysuccinic acid (ESA)

ESA, which can be used as a good starting material for the synthesis of optically active compounds such as optically specific single β -lactam antibiotics (Yamaguchi and Nogami, 1987), was first isolated from culture filtrates of *Paecilomyces variotii*, *Talaromyces flavus* (Martin and Foster, 1955), and *A. fumigatus* (Birkinshaw *et al.*, 1945). Tracer studies showed that the epoxide results from attachment of an oxygen atom into fumarate (Aida and Foster, 1962; Wilkoff and Martin, 1963). The enzyme – likely a cytochrome P450 monooxygenase – is still unknown. Culture fluids containing ESA can be further converted to meso-tartaric acid by several bacteria and fungi including *A. fumigatus* (Martin and Foster, 1955). Meso-tartaric acid has a linear 3D structure with the carboxyl groups in “anti” position, which renders it suitable for copolymer formation with diols. The reaction from ESA to meso-tartaric acid is hydratization catalyzed by fumarase (Albright and Schroepfer, 1970). It is therefore noteworthy that not even traces of meso-tartaric acid were found in culture filtrates of those fungi that produced ESA.

Tricarboxylic Acids

Citric acid

Citric acid (2-hydroxypropane-1,2,3-tricarboxylic acid) is a weak tricarboxylic acid with pK_a values of 2.92, 4.28 and 5.21 at 25°C . Since these differences are relatively small, the pH regions in which the four ionic species exist overlap heavily. As a consequence, citric acid solutions are powerful buffers – and widely used as such – between about pH 2 and pH 8. It was first isolated by the Swedish pharmacist Carl Wilhelm Scheele in 1784 from lemon juice. Indeed, citric acid may constitute up to 8% of the dry weight of lemons, oranges, limes, and other citrus fruits, and – depending on the cultivation conditions and variations within species – its concentration may reach 0.3 M in the juices. However, being the denominator intermediate of the citric acid (a.k.a. Szentgyörgyi-Krebs) cycle, citric acid is in fact an integral part of the cell metabolism of all aerobic organisms.

Industrial citric acid production began in the mid-nineteenth century in England, utilizing citrus fruits imported from Italy and Sicily. The extracted juice was treated with calcium hydroxide to precipitate citric acid into calcium citrate, and the isolated calcium salt was then converted back to citric acid using diluted sulfuric acid. The cartel-like structure of the citrus fruit growers and growing demand however, stimulated the development of other means of production. In 1893, the German chemist Carl Friedrich Wilhelm Wehmer discovered that certain filamentous fungi (molds mostly belonging to the genus *Penicillium*, but named “*Citromyces*” back then) could produce citric acid from sugar in liquid cultures. The American chemist James N. Currie (1917) demonstrated that *A. niger* strains are far superior citric acid producers to any culture resembling Wehmer’s *Citromyces* if grown on concentrated sugar solutions. The carbon source could be any kind of inexpensive sugary solution such as corn steep liquor, molasses or hydrolyzed corn starch. Up until World War II, citric acid manufacturing was performed by the labor intensive and relatively low-yield surface method – originally patented by Currie in 1923 – where *A. niger* was grown in shallow aluminum trays filled up with sugar and other nutrients (Doelger and Prescott, 1934). Sterile air passed over the pans supplied oxygen and served as cooling agent. The downstream process started with the separation of mycelia from the fermentation broth, and was followed by the isolation of citric acid from the cell-free medium by the calcium precipitation method described above. A submerged, batch-mode citric acid fermentation process employing mechanically agitated, aerated, high-quality steel vessels with several hundreds of m^3 volume was established in the USA in 1952, and was eventually introduced all across the world in the second half of the last century (Lockwood and Nelson, 1946; Perlman *et al.*, 1946a,b; Martin and Waters, 1952). Despite of minor differences in the upstream and downstream technology, all producers almost exclusively employ carefully selected strains of *A. niger* grown in highly optimized liquid medium. Today, citric acid is the largest-volume bulk product in biotechnology after bioethanol, with over 2.1 million tons manufactured globally in 2018. Well over half of this volume is now produced by Chinese companies. Being edible and fully biodegradable, it is most widely used as a flavoring agent and preservative in food and beverages, particularly soft drinks. It is also utilized as an emulsifying agent, while various metals are also delivered as citrate salts in dietary supplements. Apart from the food applications, citric acid is extensively used as acidifier and chelating agent in the chemical and pharmaceutical industries. As such, it dissolves rust from steel, passivate stainless steels, removes the buildup of limescale from evaporators, eliminates hard water stains from glass, as well as complexes calcium ions from blood preparations, thereby preventing clotting (Karaffa and Kubicek, 2019). Fueled by increasing demand – the global citric acid market is expected to grow at an annual rate of 4.9%, and reach US\$ 3.83 billion by 2025 – the *A. niger* citric acid fermentation will most likely remain an all-important segment of industrial biotechnology in the foreseeable future (See “Relevant Website Section”).

The metabolic steps leading to citric acid accumulation has been established already in the middle of the past century (Shu and Johnson, 1948; Martin and Wilson, 1951; Cleland and Johnson, 1954) and further refined in the last years (Chen *et al.*, 2014; Kirimura *et al.*, 2016). It involves the uptake of a hexose substrate from the growth medium, and predominantly glycolytic catabolism to two moles of pyruvate, their conversion into oxaloacetate and acetyl-CoA, the subsequent condensation of these two

direct precursors into citric acid in mitochondria, and finally, two consecutive, enzyme-catalyzed membrane transport steps: from mitochondria into the cytosol and through the cell membrane to the growth medium.

A massive carbon flux through the glycolytic (Embden-Meyerhof-Parnas, EMP) pathway is a fundamental prerequisite to high-yield citric acid production. However, cytosolic citrate is a strong regulator of the EMP route because it inhibits 6-phosphofructokinase and thus adjusts the rate of lipid biosynthesis (Fiechter and Gmünder, 1989). The explanation for this apparent contradiction is that under appropriate nutrient conditions, this inhibition is decisively counteracted by various positive effectors. Probably the most relevant of all is fructose 2,6-bisphosphate (Fru-2,6-P₂), whose absence renders phosphofructokinase – the key enzyme of the glycolytic pathway – practically inactive (Kubicek-Pranz *et al.*, 1990; Capuder *et al.*, 2009). On the other hand, intracellular levels of Fru-2,6-P₂ exponentially increase in the presence of high (> 10%, w v⁻¹) concentrations of rapidly assimilating carbon source, allowing intense glycolytic catabolism to proceed. Phosphofructokinase is also activated by elevated levels of intracellular ammonium ions resulting from the increased rate of protein degradation which, in turn, is prompted by manganese ion deficiency, one of the fundamental traits of the *A. niger* citric acid fermentation technology (Habison *et al.*, 1983). High glycolytic flux is additionally fueled by the intake of hexoses by a second, low-affinity glucose permease. In contrast to the high-affinity glucose transporter (K_m = 0.3 mM), this enzyme contributes to glucose uptake only at high external concentrations (Torres *et al.*, 1996; Wayman and Matthey, 2000).

The cytosolic oxaloacetate formed by the carboxylation of pyruvate is reduced to malate by the cytosolic malate dehydrogenase isoenzyme, thereby also re-oxidizing half of the glycolytically produced NADH. The cytosolic malate then enters mitochondria via a malate-citrate antiport (a tricarboxylate carrier), becomes part of the Krebs-cycle, and is thus oxidized back to oxaloacetate, one of the two direct precursors of citric acid. Citric acid formation occurs by the citrate synthase-catalyzed condensation of a CoA-activated acetyl moiety and oxaloacetate. This enzyme is located exclusively in the mitochondria, and appears to have sufficient natural capacity for citric acid overflow (Ratledge, 2000). The same is true for the other enzymes of the Krebs-cycle. Moreover, evidence proves that an intact Krebs-cycle is present throughout the citric acid fermentation, and hence theories based on the inactivation of the citric acid degrading enzymes (aconitase, isocitrate dehydrogenase) to explain accumulation are incorrect (for review, see Ruijter *et al.*, 2002). A more likely hypothesis is that the mitochondrial tricarboxylate transporter is responsible for the removal of citric acid from mitochondria (Kubicek, 1987). The provision of malate – which, as discussed above, is a counterion for the carrier – may serve as a pace maker for citrate export. In fact, an increase in the cytosolic concentration of malate precedes citrate accumulation, and gene amplification of the cytosolic malate dehydrogenase in *A. niger* has been shown to lead to increased citrate formation rates (de Jongh and Nielsen, 2008). The mitochondrial tricarboxylate carriers of higher eukaryotes generally exhibit a much higher affinity for mitochondrial citrate (K_m = 0.027 mM; Palmieri, 1994) than aconitase (K_m = 3.2 mM; Grotjohann *et al.*, 2001). This comparison suggests that the tricarboxylate carrier favorably competes with aconitase during citric acid production conditions, without any necessity for a bottleneck in the Krebs-cycle downstream of citrate.

The above-described mechanism suggest that the mitochondrial citrate/malate antiporter is a critical element of the citric acid overflow. However, knock-out of the tricarboxylate carrier gene results in a strain of *A. niger* that still accumulates citric acid with a rate of about 50% of the parental strain (Kirimura *et al.*, 2016), and the presence of other transporters for citrate is unlikely. An explanation could be that part of citrate is completely synthesized in the cytosol (Karaffa and Kubicek, 2019). This hypothesis is supported by the presence of two cytosolic isoenzymes of citrate synthase. Since pyruvate decarboxylase of *A. niger* is also located in the cytosol (see above), citrate biosynthesis would only need a cytosolic supply of acetyl-CoA. One such possibility is the oxidation of pyruvate to acetaldehyde and subsequent conversion to acetyl-CoA by an acetyl-CoA synthase (Karaffa and Kubicek, 2019). Alternatively, cytosolic acetyl-CoA can be formed by ATP-citrate lyase, whose expression is upregulated in *A. niger* under high citric acid producing conditions (Chen *et al.*, 2014). Operation of this activity involves the conversion of an ATP back to ADP and inorganic phosphate, thereby decreasing energy charge and subsequently relieving allosteric inhibition of ATP over glycolytic carbon catabolism. Both mechanisms require experimental verification though.

Export of citric acid from the cytosol to the fermentation broth is an enzyme catalyzed process. Citrate permease – like cell membrane-bound permeases in general – can transport its substrate into both directions, and under citric acid producing conditions, the *A. niger* citrate permease as an exporter has to work against a strong gradient (external concentration up to 1 M, internal concentration 4–10 mM; Habison *et al.*, 1983). The citrate permease seems to be a major bottleneck for the rate of citrate accumulation because its conditional overexpression dramatically increases the citrate production rate (Steiger *et al.*, 2019).

Itaconic acid

Itaconic acid (2-methylenesuccinic acid, 1-propene-2-3-dicarboxylic acid) is an unsaturated, weak dicarboxylic acid (pK_a = 3.83 and 5.41), discovered in 1837 as a thermal decomposition product of citric acid. The presence of the conjugated double bond of the methylene group allows polymerization both by addition and condensation. Esterification of the two carboxylic groups with different co-monomers is also possible (Kuenz *et al.*, 2012). These diverse properties have led to a variety of applications in the pharmaceutical, architectural, paper, paint, and medical industries such as plastics, resins, paints, synthetic fibers, plasticizers, and detergents. Recently, itaconic acid applications have penetrated the dental, ophthalmic and drug delivery fields (Hajian and Yusoff, 2015). Itaconic acid polymers could even replace the petroleum-based polyacrylic acid, which has a multi-billion dollar market (Saha *et al.*, 2019). Not surprisingly, the US Department of Energy assigned itaconic acid as one of the top 12 most promising building block chemicals for bio-based economy in 2004 (Werpy and Petersen, 2004). However, to fulfill its potential, the selling price of itaconic acid – currently at approximately \$2.0 kg⁻¹ – must drop considerably. Many of the plants in developed countries

have therefore relocated to China, which now accounts for the overwhelming majority of global itaconic acid production, estimated at 42,000 tons per year (Geiser *et al.*, 2016).

Little is known about the reasons why fungi produce itaconate. Like the other organic acids, as outlined above, also itaconic acid might serve as acidifier of the environment and thus provide selective advantage for the acid-tolerant *A. terreus* over other micro-organisms. However, itaconic acid also has clear inhibitory properties: in macrophages of mammals, bacterial infection prompts the induction of a gene encoding a *cis*-aconitate decarboxylase, resulting in itaconic acid formation that inhibits bacterial metabolism as part of the immune response. The effect has been attributed to the inhibition of succinate dehydrogenase and isocitrate lyase (McFadden *et al.*, 1971), the latter being a key enzyme of the glyoxylate cycle, required for the survival of pathogens inside a host. In turn, a few strains of these bacteria have evolved to be capable of degrading itaconate (Sasikaran *et al.*, 2014). Itaconic acid also induces a transcription factor which is essential for protection against oxidative and xenobiotic stresses, and to attenuate inflammation (Kobayashi *et al.*, 2013; Bambouskova *et al.*, 2018). Whether a similar function of itaconate exists in the fungi producing it has not yet been studied.

The biosynthetic pathway of itaconic acid resembles that of citric acid, the latter acid being a direct precursor of the former. The only difference is that citric acid in *A. terreus* is further metabolized via *cis*-aconitate to itaconate by *cis*-aconitate decarboxylase (Bonnamme *et al.*, 1995). To this end, *cis*-aconitate is transported out of the mitochondria by a specific antiporter in exchange for oxaloacetate (Li *et al.*, 2011a,b). Itaconic acid – formed upon *cis*-aconitate decarboxylation – is finally secreted out of mycelia by a specific cell membrane transporter. Genes encoding these three enzymes, and a fourth one encoding a transcription factor, constitute the “itaconate gene cluster” in the *A. terreus* genome, while the cluster is notably absent in *A. niger*. Although several itaconate producers have been tested, the plant pathogenic Basidiomycete *Ustilago maydis* (the corn smut fungus) – and particularly its low pH-stable relative *Ustilago cynodontis* (Hosseinpour Tehrani *et al.*, 2019b) – seems to be the only one with a reasonable chance to become another industrial platform organism (Hosseinpour Tehrani *et al.*, 2019a). *Ustilago* has developed an alternative biochemical pathway to synthesize itaconate inasmuch as *cis*-aconitate is converted to the thermodynamically favored *trans*-aconitate by aconitate- δ -isomerase. *Trans*-aconitate is then decarboxylated to itaconate by *trans*-aconitate-decarboxylase.

Sugar Acids

Gluconic acid

Gluconic acid is a non-corrosive, non-toxic, biodegradable, weak ($pK_a = 3.86$) organic acid. It mainly occurs in plants, fruits, wine, and honey. Gluconic acid is produced from D-glucose by the oxidation of its aldehyde group (C1) to a carboxyl group. It is not to be confused with other glucose-derived acids such as glucuronic acid, where C6 is oxidized to a carboxyl group, or glucaric acid, where both C1 and C6 are carboxylic groups. In aqueous solution at neutral pH, gluconic acid forms gluconate ion that is in equilibrium with its cyclic ester D-glucono δ -lactone (1, 5-gluconolactone). The equilibrium is dependent on pH and temperature; heat and high pH increase the rate of D-glucono- δ -lactone hydrolysis. Together with its salts and the δ -lactone form, gluconic acid is included as a flavoring agent in a variety of food items such as meat, wine, and dairy products. Due to its ability to form water-soluble complexes (chelates) with di- and trivalent metal ions, it is frequently applied as counterion during therapeutic calcium and/or iron administration. For the same reason, it is also used to remove calcareous and rust deposits from metals or other surfaces. Today, gluconic acid and its derivatives have an annual market volume of approximately 80,000 tons, amounting to almost 1 billion €.

In contrast to bacterial gluconic acid formation, which is a one-step process typically catalyzed by a membrane-bound D-glucose dehydrogenase, fungal gluconic acid formation consists of two steps. The first is the direct dehydrogenation of β -D-glucose to D-glucono- δ -lactone by glucose oxidase. This enzyme is a flavoprotein containing a FAD-cofactor which takes up two hydrogen atoms from D-glucose during catalysis and releases hydrogen peroxide. However, D-glucono- δ -lactone is unstable in aqueous solution. The second step – the hydrolysis of the lactone to its free form, gluconic acid – can therefore be either spontaneous or catalyzed by lactonase. Depending on the fungal genera, glucose oxidase is either a fully extracellular enzyme or partially cell wall-bound. In all cases, however, it requires molecular oxygen to regenerate FADH₂ and is inactivated at pH < 3. Therefore, the fermentation has to be carefully kept above this pH value. The *goxA* gene encoding glucose oxidase is induced by high glucose concentrations and high dissolved oxygen levels, but the enzyme is competitively inhibited by the hydrogen peroxide formed during FAD recycling. To prevent this, *A. niger* also secretes several catalases that catalyze the decomposition of hydrogen peroxide to water and oxygen. Sufficient catalase activity is in fact critical during gluconic acid fermentation. The ability of *A. niger* to form glucose oxidase may be an evolutionary advantage related to competition with other micro-organisms, as the produced hydrogen peroxide has been shown to be the causal agent in combatting other fungi. However, due to the necessity of high glucose concentrations, this mechanism only applies at special conditions. In addition, glucose oxidase activity depletes the available glucose pool in exchange for the formation gluconic acid. Gluconic acid is usually a poor carbon source for micro-organisms, but happens to be a good one for *A. niger*.

At technical scale, gluconic acid is prepared by microbial fermentation of the various bacterial and fungal strains that were shown to be capable of accumulating gluconic acid, *A. niger* is the most widely used platform organism. Gluconic acid accumulation in *A. niger* cultures was first observed in 1922. The traditional gluconic acid production with *A. niger* is named “calcium gluconate process”, which stems from the use of calcium carbonate for neutralization of the fermentation broth, a critical technological step to keep the extracellular glucose oxidase active. The production medium contains up to 150 g L⁻¹ glucose (most frequently derived from corn or rice); further increase in the glucose concentration is hampered by the limited solubility of calcium gluconate, which

would precipitate on the mycelia and inhibit oxygen and substrate uptake. Other components of the nutrient medium – particularly phosphorus and nitrogen – are kept at low levels to prevent fungal growth (= loss of carbon source). The stoichiometry of the reaction leading to gluconic acid formation shows that on a molar basis, identical amounts of oxygen and D-glucose are needed, despite of the former being much less soluble in water. Applying overpressure (up to 3 bars) in the fermentor – which, according to Henry's law, will increase the saturation level of oxygen in the medium through increasing its partial pressure – has therefore been shown to be highly beneficial. The fermentations with almost quantitative yields ($Y_{p/s} > 95\%$ on a molar basis) are short, between 24 and 48 h. In fact, the process resembles to an enzymatic conversion rather than a microbial fermentation.

Sodium gluconate has been used as a superior alternative to the calcium gluconate process, as it enables to use even higher glucose concentrations (up to 350 g L^{-1}). Here, the pH is maintained at 6.5 by external control with NaOH, but otherwise, the process is similar to the previous one. Based on this technology a continuous process was developed, converting $35\% \text{ (w v}^{-1}\text{)}$ glucose solutions with 95% yield. Another continuous fermentation method employing the osmotolerant yeast *Aureobasidium pullulans* was also described, with the advantage of enabling extremely high ($>350 \text{ g L}^{-1}$) initial glucose concentrations in the medium.

Engineering Aspects of Fungal Organic Acid Production

Industrially, organic acids are mostly produced by submerged fermentation in large, stainless-steel vessels of several hundreds of cubic meter volume to achieve $>100 \text{ g L}^{-1}$ yield (Roukas, 1991; Grewal and Kalra, 1995). In the case of citric acid, surface cultivation using large and flat pans is still used by some companies because it is much less influenced by the presence of manganese and morphological development (for review, see Show *et al.*, 2015). In addition, some companies – mainly in the China and South East Asia – use solid substrate fermentations (Kareem *et al.*, 2010).

High-rate provision of oxygen, as explained in the respective chapters, is essential for high organic acid yields (Grewal and Kalra, 1995). Apart from the control of oxygen transfer and the growth medium temperature, few other fermentation parameters are controlled. In some cases, additional substrate is fed before the end of fermentation.

The downstream processes (recovery and purification) may correspond to over 50% of the overall production costs for all organic acids (Cheng *et al.*, 2012). Downstream typically starts with filtering the fermentation broth to remove mycelia by sedimentation, centrifugation or filtration, after which the product in the cell-free medium is separated and purified to the desired extent. The two most traditional methods for organic acid isolation from cell-free broth are precipitation with Ca(OH)_2 or CaO (Heding and Gupta, 1975; Berglund *et al.*, 1998; Li *et al.*, 2016) and crystallization (Okabe *et al.*, 2009). During the former, the obtained calcium salts react with concentrated sulfuric acid and release free acid, which is further purified by active carbon absorption or ion exchange. Afterwards, the product is further concentrated and crystallized by evaporation. Advantages of precipitation are selectivity and high product purity. The three largest-market organic acids (citrate, lactate, succinate) produced by fermentation are mostly recovered by precipitation (Li *et al.*, 2016).

Crystallization of organic acids is enabled by the dependence of their solubility on the temperature: its alteration allows their concentration and subsequent crystallization, which is usually performed under vacuum.

Another frequently used separation method – chromatography – relies on the ion-exchange or adsorptive properties of resins toward organic acids (Boonkong *et al.*, 2009; Zhou *et al.*, 2011). Interactions with macroporous adsorption resins rely on the hydrogen bond and the van der Waals' force. Chromatography is typically used for the final purification of organic acids from aqueous solution, as the resin employed is highly selective. The method has low energy consumption and high capacity.

Membrane separation techniques such as microfiltration, ultrafiltration, nanofiltration, reverse osmosis (= forcing the water in the broth across a semi-permeable membrane, leaving dissolved compounds behind), pervaporation (= permeation through a membrane followed by evaporating the permeate into vapor phase), and electrodialysis have also been positively tested for organic acid recovery (Li *et al.*, 2016). However, their high capital cost and energy requirement to maintain the transmembrane flux to separate a relatively cheap product makes them uneconomical at this time.

Liquid–liquid extraction, where separation occurs based on the relative solubility of the products in two different, immiscible liquids is another means to recover organic acids (Cheng *et al.*, 2012). A non-polar organic solvent such as esters, ketones or amines takes them up first from the mother liquor which is then washed with water to recover the product. Although the conventional solvents (long-chain alcohols, esters) are not always effective due to the low distribution coefficient of some industrially relevant organic acids, the method can be improved by employing organophosphorus compounds, or tertiary and quaternary amines. A version of liquid–liquid extraction – reactive extraction – involves converting the product into another compound for easier extraction, and was adopted to extract lactic acid and succinic acid from broths (Li *et al.*, 2010).

Introduction

Xylitol ($C_5H_{12}O_5$) is a five carbon sugar alcohol, also known as polyol, naturally present in small amounts in some fruits and vegetables. It presents a sweetness profile similar to sucrose with a low caloric value (2.4 kcal g^{-1}), being partially absorbed (50%) in the small intestine and metabolized in the liver with no effect on blood glucose or insulin levels. The unabsorbed fraction that reaches the distal parts of the gastrointestinal tract is degraded by intestinal microbiota leading to the formation of short-chain fatty acids (Grembecka, 2015; O'Brien-Nabors, 2011; Salli *et al.*, 2019). Due to the low-caloric content and the insulin independent-metabolism, xylitol is widely used as sweetener in food and beverage products (chewing gums, candy, fruit drinks) and also as additive in functional foods, especially applied in diabetes management. Additionally, xylitol exhibits a unique role in caries prevention. It is not metabolically used as energy source by oral flora, reducing the growth of mutans streptococci, the group of bacteria responsible for dental caries formation. In this sense, the substitution of sugar by xylitol in food along with its incorporation in dental care products (toothpaste and mouthwash) has considerable impact on dental health (Janakiram *et al.*, 2017; Maguire and Rugg-Gunn, 2003).

In addition to these advantageous properties, xylitol has been identified as one of the 12-top value added compounds to be attained from biomass and can be also used in the chemical industry as an intermediate for the synthesis of ethylene glycol, propylene glycol, glycerol, xylaric acid, and polymers (Hernández-Pérez *et al.*, 2016; Isikgor and Becer, 2015; Werpy and Petersen, 2004).

Currently, xylitol is largely used as sweetener due to the public awareness of adverse health impacts from excessive sugar consumption. As the consumers have become more aware of the link between sugar intake, and obesity and related diseases, the replacement of simple sugars in the daily diet by low-calorie sweeteners is increasing the demand of xylitol (Chattopadhyay and Raychaudhuri, 2014; Philippe *et al.*, 2014; Toews *et al.*, 2019). The global xylitol market reached US\$875 million in 2019, with the chewing gum industry being the largest application segment of the market. Nevertheless, as the scope of xylitol applications is expanding, it is expected to reach US\$1.37 billion by 2025 (Hernández-Pérez *et al.*, 2016).

The industrial production of xylitol started in 1975 by Finnish Sugar Co. Ltd (Finland), through chemical hydrolysis and hydrogenation of xylan. Xylan is a polysaccharide composed by β -1,4-linked xylose, abundantly present in agro-industrial residues. The procedure involves acid pretreatment of these lignocellulosic materials to generate a xylose-enriched hydrolysate. The subsequently catalytic reduction of xylose to xylitol requires an additional purification step by exchange chromatography and activated carbon, being performed at high hydrogen pressure and temperature. This procedure, in spite of using a renewable feedstock lignocellulose as raw material, is not environmental-friendly, and requires expensive equipment and large amount of energy (Dasgupta *et al.*, 2017).

Biotechnological Production of Xylitol: The Yeast's Role

Xylitol Production by Native Xylose Utilizing Yeasts

Considering the growing commercial demand for xylitol together with the safety concerns related with the costly chemical process, several research efforts have been applied over the last years for the development of biotechnological production of xylitol. Bioconversion methods based on whole cell biocatalyst, including bacteria, fungi and yeast, involve milder temperatures and pressure conditions, reducing the energy requirements and thus the overall process cost. In addition, as the microbial conversion of xylose does not require high purity, the purification steps before xylose reduction are not required, which also contribute to the reduction of production costs.

Bacteria, yeasts, and filamentous fungi are naturally capable of xylitol biosynthesis. However, there are few studies regarding xylitol production by bacteria and filamentous fungi, mainly due to the low yields and reduced final xylitol concentrations. Most studies on xylitol production with filamentous fungi (*Aspergillus*, *Byssoschlamys*, *Fusarium oxysporum*, *Gliocladium*, *Myrothecium*, *Penicillium*, *Rhizopus*, and *Neurospora* sp.) reported low concentrations of xylitol with the exception of *Petromyces albertensis* that produced 39.8 g l^{-1} of xylitol after 10 days of incubation (Dahiya, 1991; Rafiqul and Mimi Sakinah, 2013). Native xylose utilizing yeasts (*Candida*, *Debaromyces*, *Kluyveromyces*) are the organism of choice for xylitol production due to their high pentose assimilation and xylose utilization capacity through the oxidoreductase pathway (Fig. 1). Xylose metabolism is catalyzed by two key enzymes: xylose reductase (EC 1.1.1.307) and xylitol dehydrogenase (EC 1.1.1.175). Firstly, xylose is reduced to xylitol by the xylose reductase (XR). This enzyme belongs to the aldose reductase family and generally uses NADPH over NADH as cofactor (Quehenberger *et al.*, 2019). The xylitol produced can be secreted from the cell or oxidized to xylulose by the xylitol dehydrogenase (XDH) which uses only NAD^+ as cofactor. Xylulose after phosphorylation to xylulose 5-phosphate is further metabolized through the pentose phosphate pathway (PPP). Xylitol accumulation is caused by a cofactor imbalance between the mainly NADPH-dependent XR and the NAD^+ -dependent XDH.

Fig. 1 Metabolic pathways involved in xylitol production by yeast.

Among yeasts, *Candida* species are the most studied for xylitol production (Table 1). In several tests, performed for comparison of different xylose utilizing-yeasts, *Candida* species showed better xylitol production capacity (Barbosa *et al.*, 1988; Gong *et al.*, 1981; Guo *et al.*, 2006; Misra *et al.*, 2012; Vandeska *et al.*, 1995). In fact, the higher specific activity of XR in comparison with XDH, could explain high xylitol accumulation by these yeasts (Yablochkova *et al.*, 2003). The highest xylitol productivity values were reported by *Candida tropicalis*. The optimization of culture conditions, namely aeration, initial xylose concentration and yeast extract supplementation, allowed to obtain a maximum xylitol production rate of $2.67 \text{ g l}^{-1} \text{ h}^{-1}$ by *C. tropicalis* IF0 0618 (Horitsu *et al.*, 1992). This volumetric productivity was further improved to $5.4 \text{ g l}^{-1} \text{ h}^{-1}$ in a cell recycle fermentation performed with complex medium (Kim *et al.*, 2004). Furthermore, Kwon *et al.* (2006b) reported a remarkable xylitol productivity of $12 \text{ g l}^{-1} \text{ h}^{-1}$ in cell-recycling strategy, using a submerged membrane bioreactor. In this study, *C. tropicalis* KCTC 10457 produced 182 g l^{-1} of xylitol with a corresponding yield of 0.85 g g^{-1} in a fed-batch fermentation of xylose and glucose. The glucose supplementation seems to be advantageous for the process, since it is used for yeast metabolism and also for cofactor regeneration.

The yeasts *Debaryomyces*, *Pichia*, and *Kluyveromyces* are also reported as natural xylitol-producing organisms (Table 1). The cultivation of *Debaryomyces hansenii* UFV-170 isolate resulted in 37 g l^{-1} , with a corresponding xylitol yield of 0.76 g g^{-1} and $1 \text{ g l}^{-1} \text{ h}^{-1}$ of productivity (Sampaio *et al.*, 2008). More recently, Himabindu and Gummadi (2015) evaluated the oxygen mass transfer coefficient in fed-batch fermentation by *Debaryomyces nepalensis* NCYC 3413, improving the xylitol yield (0.83 g g^{-1}) and final xylitol concentration (90 g l^{-1}). The use of thermotolerant yeast strains with xylose consumption ability could represent a benefit to the xylitol production process. In this regard, the yeast *Kluyveromyces marxianus* IMB2, isolated from Indian distillery, showed high-yield xylitol production (up to 0.90 g g^{-1}) but with a reduced productivity (maximum $0.24 \text{ g l}^{-1} \text{ h}^{-1}$) (Mueller *et al.*, 2011).

Despite the innate xylitol production capacity of these yeasts, genetic and metabolic engineering strategies including optimization of xylose transport system, regulation of PPP to enhance NADPH cofactor supply and knockout or/and overexpression of XDH and XR genes have been successfully applied to yeast for improving xylitol production efficiency and were recently reviewed by Dasgupta *et al.* (2017).

Exploiting *Saccharomyces cerevisiae* as Cell Factory for the Biotechnological Production of Xylitol

As mentioned above, there is a wide range of yeast strains able to produce xylitol through the xylose reductase/xylitol dehydrogenase (XR/XDH) pathway, however, xylitol is a by-product of this pathway and the yields are limited by the use of xylose as carbon source for yeast growth and maintenance energy.

Table 1 Culture conditions and xylitol concentration, productivity and yield by native xylitol-producing yeasts

The yeast *Saccharomyces cerevisiae* has been used for centuries to produce food and alcoholic beverages, and today is also applied in the pharmaceutical industry for the production of biopharmaceuticals. In addition to the GRAS status (generally regarded as safe), *S. cerevisiae* is a very attractive organism for biotechnological production processes due to the vast knowledge accumulated from years of studies and its susceptibility to genetic modifications (Ostergaard *et al.*, 2000).

Considering that *S. cerevisiae* is naturally incapable of xylose consumption due to the lack of oxidoreductase pathway, the production of enzymes with XR activity enables the conversion of xylose into xylitol in a theoretical yield of almost 100%, since the produced xylitol is not further metabolized by the yeast. The main metabolic engineering strategies that have been developed for xylitol production in *S. cerevisiae* are listed in Table 2 and are further discussed below.

The first strategy successfully applied to increase xylitol yields from xylose using *S. cerevisiae* was the production of XR, encoded by *XYL1* gene, from the xylose-fermenting *Scheffersomyces stipitis*, formerly known as *Pichia stipitis*. Since *S. cerevisiae* does not possess XDH activity, recombinant strains require a co-substrate for cell growth and regeneration of NADPH or NADH cofactors, which are essential for the enzymatic reduction of xylose by the XR (Hallborn *et al.*, 1991). Different co-substrates can be supplied to the recombinant cells for the bioconversion process. Hallborn *et al.* (1994) evaluated xylitol production using glucose, ethanol, acetic acid and glycerol as co-substrates, and only glucose and ethanol were efficiently used as carbon source. Similarly, the utilization of glucose as co-substrate improved the xylitol production by a recombinant *S. cerevisiae* harboring the *XYL1* gene from *Candida shahatae*, in comparison with the results obtained using galactose and maltose as co-substrate (Govinden *et al.*, 2001). Nevertheless, it should be taken into consideration that in *S. cerevisiae* the uptake of glucose and xylose occurs by facilitated diffusion through the same transport system (Hamacher *et al.*, 2002) and the presence of glucose competitively inhibits the transport of xylose into the cells, decreasing the xylitol productivity (Subtil and Boles, 2012). To maintain cofactor regeneration and yeast metabolism without glucose repression, a glucose-limited fed-batch fermentation strategy has been proposed for xylitol production processes. This optimized fermentation, based on a high molar ratio of xylose to glucose during the bioconversion phase, resulted in 105.2 g l⁻¹ of xylitol with an improved 1.69 g l⁻¹ h⁻¹ productivity (Lee *et al.*, 2000). A similar strategy was further applied to compare the xylitol production by expressing the *XYL1* gene from *S. stipitis* in *S. cerevisiae* using an episomal expression vector and chromosome integration (Chung *et al.*, 2002). The high xylitol productivity and improved xylose conversion rate in the recombinant BJ3505/ δ XR yeast was attributed to the stable expression of the XR encoding gene by using the multicopy chromosomal δ -integration method. In addition, the chromosomal stability of exogenous XR in this recombinant *S. cerevisiae* BJ3505/ δ XR was demonstrated in cell-recycle fermentations, resulting in 116 g l⁻¹ of xylitol and 2.34 g l⁻¹ h⁻¹ overall productivity (Bae *et al.*, 2004). Despite the reported high productivity, it should be noted that cell recycling processes require additional equipment such as fiber membrane filtration, which can increase the overall cost of the process in industrial-scale production.

In addition to glucose-limited fed-batch fermentation, transport engineering is an alternative to bypass glucose repression. The expression of the transporter-encoding gene *AraE* from *Bacillus subtilis* improved the xylitol productivity (2.47 g l⁻¹ h⁻¹) in *S. cerevisiae* expressing two copies of the *XYL1* gene from *S. stipitis* (Kim *et al.*, 2017).

Alternatively, the simultaneous utilization of cellobiose (a dimer of glucose) and xylose was proposed to prevent glucose repression since cellobiose does not inhibit xylose uptake. For cellobiose utilization, a cellodextrin transporter (*CDT1* gene) and intracellular β -glucosidase (*GH11* gene) from the filamentous fungus *Neurospora crassa* were introduced in the engineered *S. cerevisiae* expressing the xylose reductase from *S. stipitis*. The resulting D-10-BT efficiently produced xylitol by cellobiose and xylose co-consumption (Oh *et al.*, 2013).

The availability of reduced cofactors for XR activity has been identified as an important controlling factor for xylitol production. As mentioned before, XRs strongly prefer NADPH over NADH and the main source of NADPH in yeast cells is the oxidative PPP. In this sense, several research efforts have been made to control this pathway and ensure sufficient NADPH supply for an efficient xylitol production. In the PPP, NADPH is produced from NADP⁺-dependent dehydrogenases: glucose-6-phosphate dehydrogenase (G6PDH) responsible for the conversion of glucose 6-phosphate to 6-phosphogluconate, and 6-phosphogluconate dehydrogenase (6PGDH) which catalyzes the conversion of 6-phosphogluconate to ribulose 5-phosphate (Fig. 1). The overproduction of the G6PDH protein (encoded by *ZWF1* gene) increased NADPH regeneration, resulting in a 25% improvement of xylitol productivity compared to the recombinant *S. cerevisiae* strain only expressing the XR encoding gene (Kwon *et al.*, 2006a). Additionally, a

metabolic engineering approach based on the redirection of the carbon flux to the PPP by limiting the entry of a carbon into glycolysis was developed to further increase the NADPH availability in XR producing yeast. The authors have proposed the downregulation of the *PGI1* gene, coding for phosphoglucose isomerase (PGI), to reduce the conversion of glucose-6-phosphate to fructose-6-phosphate in glycolysis, resulting in accumulation of glucose-6-phosphate that can be used by G6PDH in the PPP and consequent NADPH regeneration (Fig. 1). The reduction of PGI activity alone had no positive effect on xylitol productivity but the simultaneous overexpression of the *ZWF1* gene in a recombinant PGI mutant strain resulted in 1.9-fold improvement compared with the parental strain expressing *XYL1* gene (Oh *et al.*, 2007).

The evaluation of xylitol production in terms of enzyme and cofactor preference was performed by engineering the industrial *S. cerevisiae* PE-2 strain (over)expressing different enzymes with XR activity: a NADPH-preferable native XR, a NADH-preferable mutant XR and the NADPH-dependent aldose reductase (encoded by the endogenous *GRE3* gene) that uses solely NADPH. The strains expressing enzymes with NADPH preference showed superior performance and the *GRE3*-overexpressing strain (PE-2-GRE3) was able to produce 148.5 g l⁻¹ of xylitol with 0.95 g g⁻¹ yield (Baptista *et al.*, 2018). The overexpression of the *GRE3* gene in *S. cerevisiae* ScpGT was also described as a better strategy for xylitol production, in comparison with the expression of the XR encoding gene from *S. stipitis*, *C. tropicalis*, and *N. crassa* (Kogje and Ghosalkar, 2016).

In a different approach, to overcome the preference for NADPH and allowing the simultaneous utilization of NADPH and NADH cofactors, a recombinant *S. cerevisiae* DWM-ZWF1-ACS1 overexpressing the *ZWF1* gene (G6PDH protein), was highly engineered for the production of both NADPH-preferable native XR and NADH-preferable mutant XR from *S. stipitis*, together with the overexpression of *ACS1* gene encoding for the acetyl-CoA synthetase. This enzyme is responsible for the conversion of acetate in acetyl-CoA that is further metabolized into the tricarboxylic acid cycle (TCA), resulting in NADH and NADPH regeneration. The co-production of the two types of XR with G6PDH and acetyl-CoA resulted in 196.2 g l⁻¹ xylitol with a maximal productivity of 4.27 g l⁻¹ h⁻¹ (Jo *et al.*, 2015).

Xylitol Production From Renewable Resources by Yeast

Global climate change and fossil fuel depletion have led to policies supporting carbon emission reduction and renewable energy deployment. Wastes and biomass residues from agricultural, forestry and food activities represent a valuable resource, in contrast to appropriation of edible food crops, for sustainable production of bioenergy and biochemicals (Liu and Rajagopal, 2019). Being widely available, lignocellulosic biomass is mainly composed of three polymers: cellulose, hemicelluloses, and lignin (Palmqvist and Hahn-Hägerdal, 2000). Xylan is the most abundant polysaccharide in the hemicellulosic fraction of agro-industrial residues and hardwood that can be hydrolyzed into xylo-oligosaccharides (XOS) and xylose. In terms of fully adopting a sustainable process, different environmental friendly pretreatments have been developed to obtain xylose from xylan present in hemicellulose. Dilute acid treatment is a simple, efficient and low-cost method, commonly used for xylose recovery (Table 3). Nevertheless, in a biorefinery perspective that includes the valorization of whole biomass, hydrothermal pretreatment (also known as autohydrolysis or liquid hot water) is considered a promising technology for lignocellulose biomass fractionation since it allows hemicellulose solubilization and also increases the cellulose accessibility for enzymatic hydrolysis (Ruiz *et al.*, 2020). Autohydrolysis involves only water at high temperature and pressure, without adding any other chemicals. Under these conditions, hydronium ions formed by water dissociation into H₃O⁺ and OH⁻, catalyze hydrolysis of the xylan into oligosaccharides (XOS). These XOS can be further hydrolyzed by acids or enzymes to obtain xylose (Hu *et al.*, 2016; Rivas *et al.*, 2002), which can be used for the production of xylitol. However, pretreatment of lignocellulosic biomass also generates microbial inhibitory, such as weak acids (Guo and Olsson, 2014), furans (Larsson *et al.*, 2000), and phenolic compounds (Liu *et al.*, 2004), that negatively affect cell growth and metabolism, reducing microbial fermentative performance in terms of product yield and productivity (Palmqvist and Hahn-Hägerdal, 2000). To circumvent this bottleneck, a considerable number of physical and chemical techniques for detoxification of lignocellulosic hydrolysates have been applied to remove these inhibitory compounds prior to fermentation (Kumar *et al.*, 2020). Accordingly, several studies have been using different natural xylitol-producing yeasts (*D. hansenii*, *C. tropicalis*, *Caloptilia magnolia*, *K. marxianus*) to produce xylitol from detoxified lignocellulosic hydrolysates (Table 3). Nevertheless, the additional detoxification step implies operational costs and also results in a considerable loss of sugars, which further impairs the economics of the overall process.

For the establishment of cost-efficient lignocellulose-based xylitol production it is necessary to use robust microorganisms capable of withstanding acute stresses with improved fermentative performances. The yeast *S. cerevisiae* has developed several

mechanisms to respond to the presence of inhibitors derived from different biomass pretreatments (Cunha *et al.*, 2018). In fact, *S. cerevisiae* strains isolated from industrial harsh conditions (such as elevated temperatures, pH variations and presence of toxic compounds) have proved to be less sensitive to the negative effects caused by the presence of multiple lignocellulose-derived inhibitors (Cunha *et al.*, 2018; Della-Bianca and Gombert, 2013; Pereira *et al.*, 2014). In this sense, the use of industrial isolates that naturally present desirable traits (fast sugar consumption, inhibitor and high temperature tolerance, higher detoxification capacity) could be advantageous for xylitol production in lignocellulose-based processes. Accordingly, Cortivo *et al.* (2018) developed a strategy using substrate mixture of soybean and oat hulls for ethanol and xylitol production with an industrial *S. cerevisiae* strain. Under this biorefinery concept, the recombinant YRH 396 strain expressing the XR and XDH genes of *S. stipitis* and overexpressing the native *XKS1* gene encoding the xylulose kinase (XK), which is responsible for the conversion of xylulose to xylulose-5-P (Fig. 1) produced 8.17 g l⁻¹ of xylitol and 2.9 g l⁻¹ of ethanol through the integral utilization of both residues.

Kogje and Ghosalkar (2017) engineered an industrial *S. cerevisiae* strain to overexpress the endogenous aldose reductase with XR activity (encoded by *GRE3* gene) and a xylose specific transporter from *S. stipitis* (encoded by *SUT1* gene). The *S. cerevisiae* XP-RTK strain efficiently produced xylitol (16.3 g l⁻¹) from a non-detoxified corn cob hemicellulosic hydrolysate supplemented with glucose in fed-batch mode.

More recently, Baptista *et al.* (2018) developed an efficient and environmental-friendly strategy to produce xylitol using corn cob. In this approach, the *S. cerevisiae* PE-2 industrial strain presenting innate capacity for xylitol accumulation (Romani *et al.*, 2015), robustness features in general (Pereira *et al.*, 2011), and inhibitor tolerance, in particular (Pereira, *et al.*, 2014), was engineered by overexpression of the *GRE3* gene. To obtain a sustainable xylitol production through the valorization of whole slurry corn cob (the solid and liquid fractions obtained from the corn cob autohydrolysis pretreatment), the hemicellulosic hydrolysate (liquid fraction), after hydrolysis, was used as source of xylose, while the glucan-enriched solid phase was efficiently hydrolyzed into glucose in a saccharification and fermentation (SSF) process. The glucose released was used by recombinant *S. cerevisiae* PE-2-*GRE3* cells during the bioconversion process, resulting in 29.6 g l⁻¹ of xylitol with a high yield of xylitol from non-detoxified corn cob hydrolysate (0.9 g g⁻¹). This integrated process demonstrated the feasibility of using whole slurry corn cob for xylitol production.

During the last years, consolidated bioprocessing (CBP) has emerged as a promising fermentation approach for the production of bioethanol and or other valuable products from lignocellulosic biomass. The CBP system includes enzyme production, substrate hydrolysis and fermentation in a single step, reducing the number of unit operations of feedstock processing and the overall cost of the production process (Hasunuma and Kondo, 2012). The cell surface engineering technology, based on displaying functional heterologous enzymes on the cell surface, has shown to be effective for consolidated bioprocessing of lignocellulosic materials to xylitol. Guirimand *et al.* (2016) achieved the direct conversion of xylose from rice straw hydrolysate into xylitol by engineering a *S. cerevisiae* strain to produce degrading enzymes (β -glucosidase from *Aspergillus aculeatus*, β -xylosidase from *Aspergillus oryzae* and endoxylanase from *Trichoderma reesei*) on the cell surface together with the production of the cytosolic of XR from *S. stipitis*. The recombinant YPH499-PIU-XR-BGL-XYL-XYN strain produced 5.8 g l⁻¹ xylitol with 79.5% of theoretical yield from xylose contained in the rice straw hydrolysate (Guirimand *et al.*, 2016). Although this cell surface engineered strain demonstrated xylitol production in a consolidated bioprocessing, the rate and yield of production are far below industrial requirements and need to be improved to achieve a successful process implementation.

Conclusions

Nowadays, xylitol applications are extended to several industrial sectors and the demand for healthy and low-calorie products by the modern consumers is a key factor to increase the xylitol market. The implemented manufacturing process is based on a costly chemical method that has high energy requirements. In this sense, the development of an environmental friendly and cost-competitive biotechnological process has received growing attention. Numerous xylose-fermenting yeasts have been investigated for the bioconversion of xylose to xylitol, but in spite of their natural xylitol production capacity, product yields are limited by the utilization of xylose for yeast growth and maintenance of energy. Alternatively, the use of engineered *S. cerevisiae* with increased production of enzymes with XR activity allows an easier control of the carbon sources for the bioconversion and for yeast metabolism. A considerable number of metabolic engineering approaches have been applied in recent years to convert *S. cerevisiae* into an efficient xylitol producer. Furthermore, to attain a fully sustainable xylitol production system based on renewable raw material utilization, the use of *S. cerevisiae* strains presents another advantage in terms of increased tolerance towards the presence of lignocellulosic-derived inhibitors, in comparison to non-*Saccharomyces* yeast. Although, the implementation of a cost-effective process for xylitol producing using renewable feedstocks hinges on overcoming challenges, such as biomass fractionation and effect of multiple microbial inhibitors/stressors present in lignocellulosic hydrolysates, understanding the mechanisms involved in cell-based bioconversion open new perspectives for the development of sustainable xylitol production.

A Taste of Biotechnological History

Fermented foods and beverages are not just by-products of civilization, they are central to it. Whether alcoholic beverages, such as beer and wine, were offshoots from breadmaking by the first farmers, it is clear that yeast fermentation catalyzed one of the greatest transitions in human history. From the rituals of Stone Age hunter-gathers and the origin of farming to the origin of writing and transport on wheels, one can find a possible link to yeast fermentation. All kinds of crops were fermented, and humans imbibed long before they invented the first phonetic alphabet and could count in Arabic numerals. In fact, some archeologists argue that alcoholic beverages were significant contributors to humankind's creativity, which helped foster the development of language, the arts, science and technology. They also postulate that yeast-derived alcoholic beverages inspired our hunter-gatherer ancestors to domesticate grains and fruits. The oldest firm evidence of an alcoholic beverage comes from Jiahu, China, where by 7000 BCE, a mix of rice, grapes, hawthorn berries and honey were fermented in clay jars (McGovern *et al.*, 2004).

Winemaking dates near the dawn of civilization. In the Caucasus mountains of modern-day Georgia and the Zagros Mountains of Iran as we know it today, grapes were one of the earliest fruits to be domesticated and it is estimated that wine was made as early as 7400 years ago (This *et al.*, 2006). Centuries later, with the rise of the Roman Empire, wine became the beverage of choice throughout classical antiquity. One could, therefore, think of winemaking – the fermentation of grape juice with yeast – as one of the oldest biotechnologies in the world, steeped in a long and rich history of tradition and innovation.

In today's language, biotechnology is defined as the study or application of a living organism or any of its parts to produce a product, often of commercial value. More specifically, wine biotechnology is the study of the biological fundamentals of the three main organisms involved, grapes (mostly noble varieties of *Vitis vinifera*); yeast (*Saccharomyces* and non-*Saccharomyces* species); and bacteria (malolactic bacteria of which *Oenococcus oeni* is the best known wine bacterium), as well as the fermentation and processing technologies through which grape juice is converted into flavorful wine. This chapter focuses on *Saccharomyces* and non-*Saccharomyces* yeast involved in modern-day winemaking.

The Rising Power of Wine Yeast

The French pioneer microbiologist, Louis Pasteur, was the first to emphatically demonstrate the role of yeasts during wine fermentation, in that it is the principal catalyst responsible for the conversion of grape-must sugars to alcohol and CO₂ (Barnett, 2000). In the mid-1800s, Pasteur isolated and noted different microorganisms co-existing during the fermentations, including different types of yeasts. Based on his drawings, two main yeasts were observed. The first was a small, lemon-shaped yeast abundant during the first stages of fermentation, which he called *Saccharomyces apiculatus* (now most probably known as *Hanseniaspora uvarum*). The second, which increased in abundance as the fermentation progressed, was a larger and rounder yeast, which Pasteur named either *Saccharomyces pastorianus* or *Saccharomyces ellipsoideus* (most likely the current *Saccharomyces cerevisiae*). Soon afterwards, the Swiss-German wine pioneer, Herman Müller, started recording the use of specially selected pure yeast cultures for his wine fermentations.

Now, many researchers use the term “yeast” to describe *S. cerevisiae* or closely-related species. This is mainly because *S. cerevisiae* is by far the most studied yeast and work on it has contributed greatly toward fundamental research. In 1996, it became the first completely sequenced eukaryote (Coffeau *et al.*, 1996). *S. cerevisiae* also has a widespread industrial role, used as a workhorse organism in a variety of fields, including the bioenergy and medical industries, as well as food and beverage production. *S. cerevisiae* is the main microbial player in modern-day winemaking. It is the chief fermenter of the sugars found in grape must and in most cases outcompetes other microorganisms during fermentation due to its prolific capacity to produce high concentrations of ethanol. Besides ethanol production, many *S. cerevisiae* strains also produce so-called killer factors, proteins or glycoproteins facilitated by cytoplasmically inherited double-stranded RNA viruses that are capable of entering susceptible strains (Becker and Schmitt, 2017; Wang *et al.*, 2015).

Many other types of yeasts are also present during fermentation, especially in the early phases, and do exert an influence on the final wine product as will be discussed later. These yeasts are often grouped under the term “non-*Saccharomyces* yeast” (NSY) or “non-conventional yeast” with most being closely related to *Saccharomyces*.

The Essence of Winemaking

Winemakers generate “must” from harvested grapes, involving a process of destemming, crushing and macerating the grapes. Once the must has been prepared, winemakers typically add sulfur dioxide (SO₂) to their must for three main reasons: (1) it is an

antioxidant, (2) it inhibits both bacterial and many non-*Saccharomyces* yeast growth, and (3) it is a binding partner of carbonyl and keto compound like the reactive molecule acetaldehyde. Thus, this step has a profound effect on the microbial population present to conduct the fermentation and does not impact on wine strains of *S. cerevisiae*, which have an inherent resistance to SO₂. Before 1965, winemakers allowed the natural microbial population to ferment the must, largely because of the non-existent technical capabilities to manage selected yeasts. This is known as a spontaneous fermentation. Since the late 1960s, with the possibility to produce dried yeast starter cultures, commercial yeast starter cultures became available for winemakers to add at the beginning of their fermentation and were well received. When yeast is added to must it is known as an “inoculated” or “guided” fermentation. Spontaneous fermentations are still used today to promote the sense of *terroir*, but the overwhelming majority of particularly large-scale fermentations are conducted via inoculated fermentations for the sheer consistency such a fermentation provides. Spontaneous fermentations often perform sluggishly or become “stuck” meaning the microbes in the vessel has stopped their fermenting action even though a meaningful amount of unwanted grape sugars remain. Spontaneous fermentations often perform sluggishly or become “stuck” meaning unwanted grape sugars remain even though the microbes in the vessel have stopped their fermentation action. This is difficult to remedy without affecting the quality of the resulting wine. Today, many companies world-wide provide yeast starter cultures for winemakers. At the time of writing, around 200 yeast strains, belonging to the genus *Saccharomyces*, are commercialized by only seven companies working worldwide. These catalogs of different wine yeast strains (*Saccharomyces* and non-*Saccharomyces*) have been developed to assist winemakers to create a variety of styles and must compositions. Once the so-called primary fermentation is deemed finished, meaning the majority of the sugars have been converted to ethanol, another process takes place prior to bottling. Depending on the desired wine style, a secondary fermentation known as “malolactic fermentation” could take place where malic acid is converted to lactic acid (normally conducted by lactic acid bacteria) as well as fining, filtration and maturation (often done in wooden barrels).

The vessels in which fermentations takes place can range from large steel and cement tanks to as small as an Erlenmeyer flask or a test tube which would then be called a microvinification. Microvinifications are an important research tool for testing all aspects of enology, but particularly the performance of the yeast. Promising findings from these small-scale experimentations could then be used in larger scale fermentations.

The Dominant Role of *Saccharomyces Cerevisiae*

With the aid of genomic analyzes, we know that an important genome-related event happened approximately 100 million years ago to an ancestor of the current *S. cerevisiae* yeast in that its whole genome duplicated (WGD; Kellis *et al.*, 2004). Genomic comparisons with the yeast *Kluyveromyces waltii* (a closely-related yeast which has not undergone WGD) substantiated this claim: *S. cerevisiae* has twice the number of chromosomes (sixteen versus eight), yet similar number of genes, with *K. waltii* also showing an extensive level of synteny with *S. cerevisiae*. The WGD event resulted in both massive gene loss paired with the accelerated evolution of one of the duplicated genes. Promoter rewiring of key genes involved in fermentative and respirative growth and the expansion of the alcohol dehydrogenases culminated in the *S. cerevisiae* we have today – a yeast with the ability to make ethanol even in the presence of oxygen (Piskur *et al.*, 2006). This important feature makes *S. cerevisiae* useful in both biofuel production and the beverage industry, including winemaking. *S. cerevisiae* is one of few organisms capable of converting all the sugars in a grape must to various fermentation products, but most importantly ethanol. Ethanol acts as a preservative and impacts sensory perception in wine but is most appreciated by consumers for its hedonistic value.

Yeast are not only responsible for the conversion of grape sugars to ethanol and CO₂, but also cause a total biotransformation of the grape must, as practically all components in the must are affected by yeast metabolism. Yeast perform an equally important task in the formation of aroma-active secondary metabolites, as well as in the conversion of grape aroma precursors to varietal wine aromas (Styger *et al.*, 2011). The aroma-active compounds derived from central carbon metabolism are divided into four main categories, i.e., higher alcohols, aldehydes, medium-chained fatty acids and esters (Table 1). Many of the genes involved in the pathway synthesis of aroma compound production in *S. cerevisiae* have already been identified (Dzialo *et al.*, 2017; Bisson and Karpel, 2010). There are, however, many other enzymes/gene products involved in aroma production. Some gene products that are indirectly involved in the synthesis of a given aroma compound have been identified with the aid of methods connected with reciprocal-hemizyosity analysis in order to identify quantitative trait loci (Steyer *et al.*, 2012).

Higher alcohols (also known as fusel alcohols) are, from a quantitative point of view, the most abundant category of aroma compounds produced during fermentation. The biosynthesis of higher alcohols is conducted via the catabolism of amino acids known as the Ehrlich pathway (Hazelwood *et al.*, 2008). There are three enzymatic steps: (1) transaminases would deaminate the different amino acids to their corresponding α -keto acid. Depending on the amino acid, different enzymes encoded by the genes *ARO8*, *ARO9*, *BAT1* or *BAT2* would conduct the catalysis of the first step; (2) α -ketoacids are decarboxylated to their respective aldehydes – five decarboxylases have been identified in *S. cerevisiae* to conduct this action (encoded by *PDC1*, *PDC5*, *PDC6*, *ARO10* and *THI3*); and (3) alcohol dehydrogenases, encoded by *ADH1*–6 and *SFA1*, would then catalyze the reduction of the aldehyde generating the higher alcohol. The higher alcohol hexanol is an important wine constituent but is derived from the grape must and not from yeast metabolism. Higher alcohols have a relatively high odor threshold but as most are in the milligrams per liter range, they do contribute to the overall bouquet of the final wine aroma (Lilly *et al.*, 2006). Most higher alcohols are not considered desirable, with the notable exception of 2-phenylethanol which imparts a flower/rose-like note to a wine. Higher alcohols do, however, act as substrates for acetate esters (van Wyk *et al.*, 2018).

Table 1 Important groups of aroma-active compound modulated by yeast in wine. Odor active values are as calculated in various aqueous solutions including beer, wine and water. ni = no information, nd = not detectable

Compound produced by yeast	Aroma characteristics	Reported concentration in wine (mg/L)	odor threshold (mg/L)
<i>Higher alcohols</i>			
Propanol	Stupefying	9–125	500–800
Butanol	Fusel odor	0.58	5
Isobutanol	Solvent	9–140	75
Active amyl alcohol	Marzipan	15–150	65
Isoamyl alcohol	Marzipan	45–490	7–300
Hexanol	Grassy	0.3–12	4–5.2
Tyrosol	Bees wax, honey-like	Trace	ni
Tryptophol	Phenol	Trace	ni
2-Phenethylethanol	Floral, rose	10–180	7.5–125
<i>Aldehydes</i>			
Acetaldehyde	Green, grassy	10–500	0.05
<i>Medium-chained volatile fatty acids</i>			
Butyric acid	Pungent	Trace	2.2–4
Isobutyric acid	Pungent	Trace	8.1
Isovaleric acid	Rancid, cheese, sweaty	Trace	0.7
Hexanoic acid	Rancid, fatty, pungent	nd–37	8–8.8
Octanoic acid	Oily, fatty, rancid, soapy	nd–41	13–15
Decanoic acid	Fatty, unpleasant, rancid	nd–54	8.2–10
<i>Esters</i>			
<i>Acetate esters</i>			
Ethyl acetate	Fruity, solvent, glue, balsamic	5–63.5	7.5–60
2-Methylpropyl acetate (isobutyl acetate)	Fruity, apple	nd–0.17	1.6
3-Methylbutyl acetate (isoamyl acetate)	Banana, fruity	0.03–5.52	0.03–0.16
2-Phenylethyl acetate	Rose, floral	nd–0.26	0.25–1.8
Hexyl acetate	Green, herbaceous, grape	nd–3.90	0.002–2.4
<i>Ethyl esters</i>			
Ethyl 2-methylpropanoate (ethyl isobutyrate)	Fruity, strawberry, lemon	0.01–0.48	0.001–5
Ethyl 2-methylbutanoate	Apple, strawberry, cider, anise	nd–0.03	0.0001–0.018
Ethyl 3-methylbutanoate (ethyl isovalerate)	Fruity, pineapple, lemon, anise	nd – 0.07	0.0001–1.3
Ethyl 2-hydroxypropanoate (ethyl lactate)	Fruity, milky, soapy	3.05–297.5	0.05–150
Ethyl 3-hydroxybutanoate	Fruity, green	0.05–0.58	20
Ethyl 4-hydroxybutanoate	Caramel	6.61	ni
Diethyl butanedioate (diethyl succinate)	Fruity, fermented, floral	1.21–61.11	ni
Diethyl hydroxybutandioate (diethyl malate)	Brown sugar, sweet	0.81	ni
Ethyl butanoate	Floral, Fruity, strawberry	0.07–0.53	0.001–0.4
Ethyl hexanoate (ethyl caproate)	Fruity, strawberry, green apple	0.15–1.64	0.005–0.85
Ethyl octanoate (ethyl caprylate)	Sweet, fruity, beer	0.14–2.61	0.002–0.58
Ethyl decanoate (ethyl caprate)	Oily, fruity, floral	0.01–0.70	0.012–0.51
Ethyl 3-phenylpropanoate (ethyl dihydrocinnamate)	Floral	nd – 0.003	0.002
Ethyl 3-phenylprop – 2-enoate (ethyl cinnamate)	Honey, cinnamon	nd – 0.01	0.001–0.048
Ethyl 4-hydroxy 3-methoxy-benzoate (ethyl vanillate)	Floral, sweet, vanilla	0.46	ni

Note: Values obtained from Lambrechts, M.G., Pretorius, I.S., 2000. Yeast and its importance to wine aroma – A review. South African Journal of Enology and Viticulture 21, 97–129. Sumbly, K.M., Grbin, P.R., Jiranek, V., 2010. Microbial modulation of aromatic esters in wine: Current knowledge and future prospects. Food Chemistry 121, 1–16.

The aldehydes generated during amino acid catabolism are generally quickly converted to alcohols and are thus not found in meaningful levels in wine, with the only major aldehyde produced by *S. cerevisiae* metabolism being acetaldehyde (Liu and Pilone, 2000). Acetaldehyde comprises over 90% of the total aldehyde content in wine (Romano et al., 1994). Pyruvate, an α -keto-acid, and the end-product of glycolysis is decarboxylated via the action of gene products encoded by *PDC1*, *PDC5*, and *PDC6* to acetaldehyde. Acetaldehyde is further converted to ethanol via the action of several alcohol dehydrogenases with Adh1p being the most prominent. Adh2 is responsible for the catalysis of the reverse reaction converting ethanol back to acetaldehyde. Acetaldehyde imparts a pleasant fruity aroma to wine at low concentrations but is considered an off-flavor when in excess providing an unpleasant grassy green note to wine. Depending on the yeast and style of winemaking levels of acetaldehyde can vary considerably ranging from 10 to 300 mg/L. Besides its role in aroma, it reacts with SO₂ forming a complex that reduces the antimicrobial and antioxidative effect of SO₂ addition. Acetaldehyde is also involved in the condensation reactions of anthocyanins with tannins which results in a stable wine pigment in red wines (Chen et al., 2018).

Medium-chain volatile fatty acids are synthesized by yeasts as intermediates in the biosynthesis of long-chain fatty acids (Lambrechts and Pretorius, 2000). They do impact, to a lesser degree, the final aroma but are more important in providing the carboxylic acid moiety in the production of ethyl esters. Acetyl-CoA is considered the starting molecule in the biosynthesis of fatty acids and is formed by the oxidative decarboxylation of pyruvic acid. Two enzyme systems, acetyl-CoA carboxylase (encoded by *ACC1*) and the fatty acid synthetase complex, continue in converting acetyl-CoA to malonyl-CoA and elongating the chain of fatty acid. Depending on their solubility, fatty acids can also act as potential inhibitors and thus affect the fermentation capability of yeast.

Esters (grouped into acetate esters and ethyl esters) are arguably the most sought-after group of compounds imparting fruity and floral aromas to the wine bouquet (Sumbly *et al.*, 2010). Acetate esters are derived from the condensation reaction from an alcohol and acetate-CoA whereas the ethyl esters result from the condensation reaction between an acyl-CoA (derived from medium-chain fatty acids) and ethanol. In general, esters possess a far lower odor threshold than their respective alcohol or fatty acid counterparts. The most prominent ester produced by yeast, ethyl acetate, can be considered either an acetate ester or an ethyl ester. In *S. cerevisiae*, the enzymes that drive these reactions have been identified. The two alcohol acetyltransferases Atf1p and Atf2p are chiefly responsible for acetate ester synthesis (Lilly *et al.*, 2006, 2000) with Eeb1p and Eht1p conducting ethyl ester synthesis (Saerens *et al.*, 2006). The enzyme Eat1p has also been implicated in ethyl acetate synthesis (Kruis *et al.*, 2018, 2017). The isoamyl-hydrolyzing esterase (Iah1p) has been shown to hydrolyze esters and convert them back to their respective higher alcohol (Lilly *et al.*, 2006; Fukuda *et al.*, 1998).

There are other compounds that form part of the central metabolism that could also impart flavor to the final wine product which are acetoin, 2,3-butanediol, α -acetolactate and diacetyl (Romano and Suzzi, 1996). Diacetyl, the only one with a low odor threshold, can impart an overall negative buttery note. As discussed in Romano and Suzzi (1996), there are various interconnected pathways in which *S. cerevisiae* can produce these metabolites, with diacetyl being formed either enzymatically from acetaldehyde or be converted non-enzymatically via α -acetolactate.

Sulfur-containing compounds also form a large class of wine volatiles that are extensively modulated by *S. cerevisiae*. Central to sulfur metabolism is the molecule hydrogen sulfide (H_2S), which is largely produced via the sulfate assimilation pathway during winemaking conditions (Huang *et al.*, 2017). It has a low odor threshold with a highly undesirable rotten egg aroma. Many factors contribute to excessive H_2S production, but this often occurs in grape must low in assimilable nitrogen. In general, the sulfur compounds that are intermediates in the central sulfur metabolism impart undesirable notes to the wine when excess amounts are produced (Swiegers and Pretorius, 2007; Lambrechts and Pretorius, 2000).

In contrast to the sulfur compounds discussed above, there are certain varieties of grape must that contain a significant amount of so-called varietal thiols that impart desirable notes to a wine (Ruiz, *et al.*, 2019a; Swiegers and Pretorius, 2007). The best studied varietal thiols are 4-mercapto-4-methylpentan-2-one, 4-mercapto-4-methylpentan-2-ol and 3-mercaptohexan-1-ol, which impart box tree, broom, passion-fruit, guava and conifer aromas to a wine and have all exceptionally low odor thresholds. These compounds are often bound to a glutathione, cysteine or cysteine-glycine moieties in the must rendering them non-volatile. These bound thiols are capable of entering the yeast where functional carbon-sulfur lyases (Irc7p and Str3p) can release the thiol from its bound precursor (Holt *et al.*, 2011; Roncoroni *et al.*, 2011). There are other compounds particular to certain varieties of grape must – the most prominent are terpenes – and these are highly variable among vintages. They occur either already in free form or are bound to a sugar moiety. Although conflicting data exist, it is generally considered that *S. cerevisiae* strains do not possess the enzymatic capability to release terpenes from their bound precursors in wine, but there are proven activities from non-*Saccharomyces* which will be discussed later.

There are many other modulatory effects that *S. cerevisiae* has on transforming the grape must into wine. *Saccharomyces* has some effect on acid composition, as it can produce acetic acid (the major constituent of the volatile acidity of wine) and can have slight effects in the main wine acids, i.e., malic and tartaric acid levels. *S. cerevisiae* can also affect the color by modulating the anthocyanin composition of red wines (Benito *et al.*, 2011) and the haziness by producing pectinases (Fernández-González *et al.*, 2005; Vilanova *et al.*, 2000). Thus, the choice of yeast(s) for grape must fermentation is crucial for its impact on the final wine product.

Genomics of *Saccharomyces Cerevisiae*

Parallel to our increased understanding of the role of yeast in winemaking is the advancements in genomics. We have come a long way since the first sequencing of a yeast strain in 1996, with many companies now offering competitive pricing for the sequencing of entire genomes of organisms. The genomes of yeasts are routinely sequenced in many laboratories and it is not uncommon to find literature where the whole genome of multiple strains of yeast were eventually sequenced; either for comparative studies or to validate their findings (Borneman *et al.*, 2016; Gallone *et al.*, 2016). In addition, the development of user-friendly software to process and analyze the large amount of data generated from sequencing has made genome analysis significantly easier for researchers.

The 1996 sequence of the laboratory strain S288c (Goffeau *et al.*, 1996) along with subsequent revisions (Engel *et al.*, 2014) provided a complete map of the open reading frames in *S. cerevisiae* and enabled researchers to construct a knock-out library of this strain. The knock-out library contains null mutants of most of the non-essential genes (Brachmann *et al.*, 1998). This library has been invaluable to assign functions to genes; even extrapolating to human homologs.

The first whole genome of a wine yeast was performed on the haploid strain of AWRI1631 (a spore from the N96 wine strain; Borneman *et al.*, 2008) and currently efforts have been made to generate a knock-out library of AWRI1631 akin to the one made for S288c (Peter *et al.*, 2018). As the sequences of more wine and non-wine strains became available, a clearer picture of the

Fig. 1 Genomic features that have been identified in wine *S. cerevisiae* strains. Based on Belda, I., Ruiz, J., Santos, A., van Wyk, N., Pretorius, I.S., 2019. *Saccharomyces cerevisiae*. Trends in Genetics 35, 956–957.

genomic make-up of a wine yeast and how it differs from other *Saccharomyces* strains was revealed (Eldarov *et al.*, 2018; Borneman *et al.*, 2016; Ibáñez *et al.*, 2014; Dunn *et al.*, 2012; Hyma *et al.*, 2011; Novo *et al.*, 2009). Introgressed genes and horizontal gene transfers (HGT) played significant roles in the divergence of wine strains from other *Saccharomyces* strains. Fig. 1 shows some of the major genomic features found in wine strains. A remarkable genomic trait that some wine strains contain are the three regions known as Region A, B and C presumably obtained via HGT from the wine yeasts *Torulaspora* spp., *Zygosaccharomyces bailii* and *Torulaspora microellipsoides*, respectively.

Interestingly, as more genome analyzes are being conducted on *S. cerevisiae* strains it becomes evident how genomically similar many of the commercial strains are compared to the global pool of *S. cerevisiae* diversity (Borneman *et al.*, 2016).

Genetic Modification of Wine Yeast

S. cerevisiae possesses an extensive and sophisticated genetic modification toolbox with which researchers can manipulate its genome. Most of the initial development of this toolbox was undertaken on haploid laboratory strains, most notably the S288c or BY series of strains, which was the first strain whose whole genome was sequenced (Goffeau *et al.*, 1996). These laboratory strains often possess auxotrophic mutations in genes involved in nucleotide or amino acid biosynthesis and thus cannot grow in media without the presence of the specific nucleotide/amino acid. Restoration of growth occurs with the introduction of functional copies of these specific genes and can serve as selection markers for transformation. The most common auxotrophic genes are *URA3*, *LEU2*, *TRP1*, *HIS3*, *ADE2*, *LYS2*, *MET15* and *ARG2*. As *S. cerevisiae* naturally harbors multicopy episomal plasmids (2 μ), many manipulations are based on this feature. Centromeric plasmids (low copy number), which contain a chromosomal-like autonomous replicating sequence (ARS) along with a part of a centromere sequence instead of a 2-micron sequence, are also common. A whole series of pRS-based *E. coli*/*S. cerevisiae* shuttle vectors (both episomal and centromeric) have been constructed and are publicly available (Tomlin *et al.*, 2001). With the notable exception of the T₇₃ wine yeast strain, which has an uracil auxotrophy, wine strains are prototrophic (no mutations in the genes involved in amino acid or nucleotide biosynthesis pathways) and thus require dominant selection which often involves antibiotic resistance. Resistance cassettes against the antibiotics zeocin,

hygromycin, geneticin and nourseothricin are often used. Due to the concern over the exposure of antibiotic resistance markers in foodstuffs, non-antibiotic dominant markers have been developed which include the sulfometuron, cycloheximide, or *p*-fluorophenylalanine or high levels of $\text{Na}_2\text{S}_2\text{O}_5$ which targets the native versions of *Ilv2p*, *Cyh2p*, *Aro4p* and *Fzf4p*, respectively (Cebollero and Gonzalez, 2004). Introduction of a mutant version or the overexpression of the yeast gene would allow for the successful selection of yeast transformants. Regardless of the selectable marker used, wine yeast cannot realistically maintain plasmids with auxotrophic or antibiotic markers in a winemaking setting thus stable integration of a particular manipulation is desired. This would involve targeting regions within the genome of the yeast with little to no enological contribution for example the *HO* locus. Genomic looping out methods have also been developed with the aim to eventually remove resistance markers from the genome of transformants (Walker *et al.*, 2003).

Even though various types of protocols have been developed to introduce DNA into yeast cells (Kawai *et al.*, 2010), the overwhelming majority are based on either exposing the exponentially-grown yeast to a lithium acetate/polyethylene glycol solution followed by a heat-shock (Gietz and Woods, 2002) or electroporation (Benatuil *et al.*, 2010).

Many genes of enological relevance have been identified as has been discussed earlier. Manipulation of the yeast genes either by modulating their expression, genetically removing them, or mutating important amino acid, played a crucial role in our current understanding of the function of these genes in yeast – especially in a winemaking context. The term “self-cloned” can be applied to such a genetically modified (GM) yeast when little to no foreign DNA is present. This will be greatly improved with the advent of the precision editing techniques spearheaded by CRISPR/Cas9-based genome editing as has already been demonstrated in wine yeast (van Wyk *et al.*, 2020a; Muyssson *et al.*, 2019; Vigentini *et al.*, 2017).

Many foreign or recombinant genes have been expressed in wine yeast and were subsequently used to make a wine on a laboratory-scale. Examples of the foreign genes expressed in wine yeast, and their impact of wine are shown in Fig. 2. Although the majority of efforts focus on improving or diversifying the aroma composition, some cases also addressed other enological issues like contamination or acidity.

Currently, two GM yeasts have been approved for use by the Food and Drug Administration (FDA) in the United States of America. The flagship GM yeast ML01 contains two heterologous genes: a malolactic conversion gene from *O. oeni* and a malate transport gene from *Schizosaccharomyces pombe*. This manipulation enabled the yeast to effectively transport malate and convert it to lactate. This was a revolutionary step in winemaking. For the first time, *S. cerevisiae* yeast could be used for meaningful malolactic fermentation and subsequently eliminate the need for lactic acid bacteria (LAB). This streamlined the winemaking process as malate-to-lactate conversion by bacteria is often marred by unpredictable outcomes. In addition, biological amines, like histamine, released by LAB are often present in the final wine product to which some individuals can have a reaction, such as a headache. This yeast has been in the development since 1997 (Volschenk *et al.*, 1997) and has shown to perform equally well during all aspects of growth kinetics as its parental strain (Husnik *et al.*, 2007). This was substantiated with subsequent transcriptome and proteome analyzes which showed negligible change compared to its parent (Husnik *et al.*, 2006). ML01 has been permitted for commercial winemaking since 2003 in the USA, and 2006 in Canada with Moldova being the only country allowing its use in Europe. The dispersal of this strain has been under scrutiny as it was shown to survive years after dissemination in a mock trial (Grossmann *et al.*, 2011) with qPCR-based methods being developed to detect its presence (Vaudano *et al.*, 2016).

The second authorized strain (ECMo01) can consistently degrade urea, which can spontaneously react with ethanol within wine fermentations to form ethyl carbamate, a suspected carcinogen to humans. The ECMo01 strain is a self-cloned strain containing an additional copy of the urea amidolyase gene *DUR1,2* which can catalyze the hydrolysis of urea (Coulon *et al.*, 2006). The additional copy is under the transcriptional control of a strong *PGK1* promoter allowing for the constitutive expression of the *DUR1,2* gene. This strain performs equally well as its parent under wine-making conditions, but markedly less ethyl carbamate is present in the final wine product. This strain has been approved for use in the USA and Canada since 2006, but little follow-up data exist on its use in practice.

In other fields, GM yeast strains have been used for industrial food applications. In Japan, self-cloned yeast strains have been developed for the use in sake production in 2001, after such strains were exempted from the Japanese government's guidelines for genetically modified food (Kitagaki and Kitamoto, 2013). Recently, Lallemand licensed a beer yeast strain expressing a lactate dehydrogenase from a lactobacillus for distribution in the USA (Rice, 2019).

The broader use of GM wine yeast has been a controversial topic of discussion (van Wyk *et al.*, 2019; Ramón and González, 2011; Cebollero *et al.*, 2007; Bisson, 2004). There are also vigorous attempts to develop new strains using breeding techniques specifically to avoid GM approaches (Pérez-Torrado *et al.*, 2015). Although the literature provides a convincing case for more large-scale trials, there is still an overall negative public sentiment towards the implementation of any kind of genetic modification in winemaking.

The Role of Non-Saccharomyces Yeast

As mentioned earlier in this chapter, there is a large number of yeast genera besides *Saccharomyces* present during the entire process of winemaking and are collectively called “non-Saccharomyces yeast” (NSY). The term “non-conventional yeast” is also commonly used to describe this group. Monitoring the dynamics and succession of the yeast population in the vineyard as well as during fermentation has been the subject of many studies (Varela and Borneman, 2017; Pretorius *et al.*, 1999). Interestingly, *S. cerevisiae* strains have an insignificant presence throughout the growth of the grape berries in the vineyard and is rarely the most dominant population at the commencement of fermentation. In Table 2, the yeast genera commonly isolated from vineyards and vineries are listed.

Fig. 2 Examples of foreign genes expressed in wine yeast with their subsequent enological consequence. Reference for acid modulation (Volschenk *et al.*, 2001; Dequin *et al.*, 1999); *de novo* synthesis of terpenes (Pardo *et al.*, 2015; Herrero *et al.*, 2008); increased release of volatile thiols (Swiegers *et al.*, 2009); release of varietal aroma components (Manzanares *et al.*, 2003; Ganga *et al.*, 1999); bacteriocin production (Schoeman *et al.*, 1999); decrease in ethanol levels (Malherbe *et al.*, 2003); increase in resveratrol levels (Sun *et al.*, 2015; González-Candelas *et al.*, 2000); novel aroma compounds (Lee *et al.*, 2016).

It should be noted that the taxonomy of yeast is ever-changing especially since DNA sequence analysis is now almost exclusively used for identification and classification as prescribed by the International Code of Botanical Nomenclature (McNeill *et al.*, 2012). Major overhauls in the classification of yeast occur regularly as cataloged by *The Yeast handbook* (Kurtzman *et al.*, 2011). Thus, the names of species and genera mentioned in older papers might not be in use anymore. Most relevant is *Kluyveromyces thermotolerans*, which has been reclassified as *Lachancea thermotolerans*, whereas *Candida pulcherrima*, *Candida zemplinina* and *Candida stellata* have been renamed to *Metschnikowia pulcherrima*, *Starmerella bacillaris* and *Starmerella bombicola*, respectively. As molecular techniques used to identify and distinguish between different strains become more sophisticated, strains known by a certain name often are reclassified, as was the case when some *S. bombicola* strains isolated from wine fermentations were in fact *S. bacillaris* (Csoma and Sipiczki, 2008). The teleomorph-anamorph concept which groups genera based on their sexual states are also falling out of favor and hence the *Hanseniaspora* name is preferred over the *Kloeckera* name.

At the start of most spontaneous must fermentations, yeast that are found on the berry skins, notably belonging to the *Hanseniaspora* genus, tend to dominate by sheer numbers (Martin *et al.*, 2018; Albertin *et al.*, 2016; Fleet, 2003). The composition of the yeast population shifts dramatically throughout the fermentation, as the sugar and available nitrogen levels drops, the oxygen availability decreases, the osmolarity changes and the ethanol levels rise. The addition of SO₂ to the must prior to fermentation also has a profound effect on the microbial population as it kills and limit the growth of many bacteria and NSY (Pateraki *et al.*, 2014; Constantí *et al.*, 1998). At the end of a successful fermentation, members of the *Saccharomyces* genus tend to be the dominant population.

As inoculated fermentations became a mainstay enological practice, it was a widely accepted notion that the presence of any other yeast in the fermentation would contribute toward spoilage. This is a valid argument in certain cases notably the *Brettanomyces/Dekkera* species which can produce 4-ethyl-phenol and other vicinal diketones which, when they reach high enough levels (over 600 µg/L), contribute unpleasant aromas to wines, such as aromas described as “barnyard”, “burnt plastic”, “wet animal” and “horse-sweat” commonly known as “brett” taint (Schifferdecker *et al.*, 2014). Many other yeasts can also contribute to off-flavors like *Hanseniaspora*

Table 2 Yeast genera commonly isolated from vineyards grouped in their respective classes

Ascomycota	<i>Starmerella</i>
<i>Dothideomycetes</i>	<i>Torulaspora</i>
<i>Aureobasidium</i>	<i>Wickerhamomyces</i>
<i>Saccharomycetes</i>	<i>Yarrowia</i>
<i>Brettanomyces</i>	<i>Zygoascus</i>
<i>Candida</i>	<i>Zygosaccharomyces</i>
<i>Citeromyces</i>	<i>Schizosaccharomycetes</i>
<i>Debaryomyces</i>	<i>Schizosaccharomyces</i>
<i>Hanseniaspora</i>	Basidiomycota
<i>Issatchenkia</i>	<i>Microbotryomycetes</i>
<i>Kluyveromyces</i>	<i>Rhodotorula</i>
<i>Lachancea</i>	<i>Sporidiobolus</i>
<i>Lodderomyces</i>	<i>Tremellomycetes</i>
<i>Metschnikowia</i>	<i>Bulleromyces</i>
<i>Meyerozyma</i>	<i>Cryptococcus</i>
<i>Pichia</i>	<i>Ustilaginomycetes</i>
<i>Saccharomyces</i>	<i>Rhodospidium</i>
<i>Saccharomycodes</i>	

Note: Liu *et al.*, 2017b; Mateo and Maicas, 2016; Jolly *et al.*, 2005.

which can produce high amounts of ethyl acetate imparting a nail polish odor (Hu *et al.*, 2018b). Several other genera like *Pichia*, *Saccharomycodes* and *Zygosaccharomyces* do not necessarily contribute negatively towards the aroma profile, but they do possess spoilage characteristics and have been implicated in cloudiness or sediment formation of the final wine product (Loureiro and Malfeito-Ferreira, 2003). Risk of refermentation leading to CO₂ build-up and overpressure after bottling can also be caused by spoilage organisms.

In the past 15 years, however, new light has been cast on the role of NSY in winemaking and it is now widely accepted that NSY can provide beneficial attributes to the final wine product. Thus, substantial efforts have been directed towards employing NSY in so-called co-culturing fermentation experiments, as highlighted in several reviews (Comitini *et al.*, 2017; Mateo and Maicas, 2016; Ciani and Comitini, 2015; Jolly *et al.*, 2014; Ciani *et al.*, 2010). The term “multi-starter” or “mixed culture” fermentation can also be applied for these types of fermentations. A common motivation for using NSY is to enhance the complexity and augment the diversity of the flavor profile of wine.

Table 3 shows co-culturing experiments and it is clear from the literature that a large variety of NSYs have already been tested to assess their enological potential. There are only a few species that have repeatedly shown to provide some level of benefit to the point that commercial preparations have been developed. These are *Torulaspora delbrueckii*, *Lachancea thermotolerans*, *Metschnikowia pulcherrima*, *Pichia kluyveri*, *Schizosaccharomyces pombe* and *Starmerella bacillaris* (Table 4).

There are five main benefits of employing NSYs in winemaking that have been reported in co-culturing experiments (Fig. 3): First, some NSY possess so-called aroma-releasing enzymes which in turn can be divided into two categories: (1) glycosidases which can release terpenes bound to sugar moieties in the must; and (2) carbon-sulfur lyases which release thiol molecules from the bound precursors. The yeasts *T. delbrueckii*, *M. pulcherrima* and *P. kluyveri* have been repeatedly implicated to perform this action of releasing aroma-active molecules from their bound precursors (Belda *et al.*, 2017b; Anfang *et al.*, 2009). A second benefit is that NSY can modulate the acid profile of the wine. For instance, *S. pombe* can efficiently convert malic acid to lactic acid, which reduces the overall tartness of wine (Mylona *et al.*, 2016). Wine fermented with *T. delbrueckii* strains often report much lower concentrations of acetic acid concentrations which, at high levels, can lead to a faulty wine (Benito, 2018). A third advantage is that many NSY tend to make more glycerol than *S. cerevisiae*, which diverts grape sugars away from ethanol production and thus co-culturing often leads to wine with lower ethanol levels (Goold *et al.*, 2017; Ciani *et al.*, 2016). Fourthly, since the regulation of the production of aroma-active compounds like esters, fatty acids and higher alcohols is different in NSYs than *S. cerevisiae*, the majority of coculturing experiments report vastly different aroma profiles including, at times, significantly higher levels of certain classes of aroma compounds resulting in a sensorially superior wine. A fifth benefit is that NSY have been shown to increase the polysaccharide and oligosaccharide content in wine – in particular mannoprotein release from cell walls. Their presence has been implicated in several positive qualities in wine including the prevention of the tartaric acid crystallization and protein haze formation along with increasing the sweetness, body and mouthfeel (Ruiz *et al.*, 2019b; García *et al.*, 2017).

There are other beneficial attributes that NSY can impart on the final wine product but have not been explored in coculturing experiments to a great extent. NSY, notably *S. pombe*, have been shown to modulate the anthocyanin structure of red wines by forming adducts of vinylphenolic pyranoanthocyanin which enhances color stability (Chen *et al.*, 2018; Benito *et al.*, 2011).

NSY can also provide selective antimicrobial activity. Just as with certain *S. cerevisiae* strains, many NSY possess so-called killer activity and have been shown to kill yeast known to cause spoilage like members of the *Dekkera/Brettanomyces* genus (Mehlomakulu *et al.*, 2017; Comitini and Ciani, 2011; Comitini *et al.*, 2004; Yap *et al.*, 2000). Apart from the killer toxins isolated from *T. delbrueckii* (Leticia *et al.*, 2016), and to some extent *W. anomalus* (Cecarini *et al.*, 2019), most of the other NSY studied for their killer activity in a wine setting are not known for any other enological features. These include *Candida pyralidae* (Mehlomakulu *et al.*, 2017),

Table 3 List of coculturing grape must fermentations conducted with a non-*Saccharomyces* yeast partnered with a *Saccharomyces* species along with a noteworthy outcome of the final wine. Mode of inoculations: Seq = sequential, Imm = immobilized, Sim = simultaneous

Non- <i>Saccharomyces</i> yeast	Mode of inoculation	Noteworthy enological outcomes from mixed-culture fermentations	Reference
<i>Candida cantarellii</i>	Sim, Seq	Higher glycerol and lower ethanol levels in Syrah wines	(Toro and Vazquez, 2002)
<i>Candida railenensis</i>	Seq	Increased terpene release in Muscaris wines	(van Wyk <i>et al.</i> , 2020b)
<i>Candida sake</i>	Sim	Increased ester content in Pedro Giménez wine	(Maturano <i>et al.</i> , 2015)
<i>Cryptococcus flavecens</i>	Seq	Higher glycerol and acetic acid levels in Pinotage and Sauvignon blanc wines	(Rossouw and Bauer, 2016)
<i>Debaryomyces hansenii</i>	Seq	Increased terpene release in Muscaris wines	(van Wyk <i>et al.</i> , 2020b)
<i>Debaryomyces pseudopolymorphus</i>	Sim	Increased release of terpenes in Chardonnay	(Cordero Otero <i>et al.</i> , 2003)
<i>Hanseniaspora guilliermondii</i>	Seq	Increased in phenylethanol in Fiano wine	(Testa <i>et al.</i> , 2020)
	Seq	Decreased acetic acid levels in Campanino wine	(Lombardi <i>et al.</i> , 2018)
	Sim	Higher levels of phenylethyl acetate in Malvasia Fina and Arinto wine	(Barbosa <i>et al.</i> , 2015)
	Sim	Increased ethyl esters in Malvasia Fina and Arinto wine	(Lage <i>et al.</i> , 2014)
	Sim	Higher levels of certain sulfurous compounds in an unspecified wine	(Moreira <i>et al.</i> , 2008)
	Sim	Increase acetate esters in Bobal wine	(Rojas <i>et al.</i> , 2003)
<i>Hanseniaspora opuntiae</i>	Seq	Lower ethanol yield in Pinotage and Sauvignon blanc wines	(Rossouw and Bauer, 2016)
<i>Hanseniaspora osmophila</i>	Imm-Seq	Increase isoamyl acetate in Verdicchio wine	(Canonico <i>et al.</i> , 2016)
	Sim	Increase in 2-phenethyl acetate levels in Bobal wine	(Viana <i>et al.</i> , 2009)
<i>Hanseniaspora uvarum</i>	Sim, Seq	Increase in ethyl ester levels in Cabernet Gernischt	(Hu <i>et al.</i> , 2018a)
	Sim	Increased C13-norisoprenoids, terpenes, and ethyl esters in Cabernet Sauvignon	(Hu <i>et al.</i> , 2018b)
	Seq	Increased 2-phenethyl acetate content in Bolero, Rondo and Regent wines	(Liu <i>et al.</i> , 2017a)
	Seq	Decreased ethanol levels in Pinotage and Sauvignon	(Rossouw and Bauer, 2016)
	Sim	Increase in isoamyl acetate in Negroamaro wine	(Tristezza <i>et al.</i> , 2016)
	Sim	Decreased ethanol levels in synthetic wine	(Wang <i>et al.</i> , 2016)
	Sim	Higher levels of isoamyl acetate in an unspecified wine	(Moreira <i>et al.</i> , 2008)
	Sim	Decreased ethanol levels in an unspecified wine	(Mendoza, <i>et al.</i> , 2007)
	Seq	Lower medium-chained fatty acid content in Chelva wines	(Herriaz <i>et al.</i> , 1990)
<i>Hanseniaspora vineae</i>	Sim, Seq	Increase higher alcohols and acetate esters in Vidal Blanc icewine	(Zhang <i>et al.</i> , 2018b)
	Seq	Higher glycerol and ester levels with lower alcohols and fatty acids in Chardonnay	(Medina <i>et al.</i> , 2013)
	Seq	Increase in 2-phenylethyl acetate in Tempranillo wine	(Viana <i>et al.</i> , 2011)
<i>Issatchenkia orientalis</i>	Sim	Reduction of malic acid in Campbells early wines	(Kim <i>et al.</i> , 2008)

Pichia membranifaciens (Belda *et al.*, 2017a), *Tetrapisispora phaffii* (originally called *Kluyveromyces phaffii*; Comitini *et al.*, 2004) and *Ustilago maydis* (Santos *et al.*, 2011). Thus, it is proposed to separately propagate and isolate the killer toxin, which could then be added to the fermentations, rather than co-culturing the NSY with *S. cerevisiae* (Mannazzu *et al.*, 2019). The mechanisms of the killer activity of these NSY strains have, in some cases, been elucidated, identifying that many bind to glucan and plasma membrane receptors, possessing cell wall degrading capabilities. Upon entry into the cell, the killer toxin can cause a variety of cell damage leading to cell arrest and apoptosis (Cecarini *et al.*, 2019; Liu *et al.*, 2015; Comitini *et al.*, 2009). It should be noted that, for unknown reasons, not all members of the *Brettanomyces*/*Dekkera* genus are equally susceptible to a specific killer toxin and are, in fact, not affected by its presence (Santos *et al.*, 2011; Yap *et al.*, 2000). Yet successful implementation of killer toxins in wine could dramatically minimize the use of pre-fermentative SO₂ additions.

It is not known whether *M. pulcherrima* produces any kind of killer toxin, but it does produce a significant amount of pulcherriminic acid – a precursor to the pulcherrimin pigment – which can have a wide-scale antimicrobial effect, absorbing iron within its

Table 4 Commercially available non-*Saccharomyces* strains (as of April 2020)

**Fig. 3** Major impacts of non-*Saccharomyces* yeast (NSY) on winemaking. Noteworthy NSYs are mentioned for each influence. Other yeast examples are in [Table 3](#). Color stability and killer activity are included though few examples in the literature exist of coculturing must fermentations.

environment and depleting it for other populations (Oro *et al.*, 2014). Pulcherriminic acid and pulcherrimin can also inhibit the fermentative capability of *S. cerevisiae* and are thus incompatible with certain *M. pulcherrima* strains in a co-culturing fermentation.

An important consideration for co-culturing strategies is the order should of the inoculations known as the modality of inoculations. The most popular mode is sequential inoculation where the NSY is inoculated first and ferments alone for a couple of days, before the *Saccharomyces* strain is added. Once co-cultured with *S. cerevisiae* (which turns the environment anaerobic, producing ethanol and killer toxins), many aerobic NSY strains cease fermentation when oxygen is depleted and have a negligible effect on the final wine. The other mode is known as simultaneous inoculations where the NSY and *Saccharomyces* strains are added at the same time in the beginning of the fermentation. There are couple of examples where sequential and simultaneous co-culturing have been conducted within the same experiment and it is clear that the choice can have a profound effect on the final wines being produced (Hu *et al.*, 2018a, 2018b; Zhang *et al.*, 2018b; Zironi *et al.*, 1993). Immobilized non-*Saccharomyces* cells have also been used in coculture fermentations with examples shown in Table 2. Cells are often encapsulated (or immobilized) within alginate beads and added to the must, often performed with a sequential type of inoculation. This method greatly improves the removal of the yeast cells and is useful if unwanted by-products are known to be produced by the NSY with long incubations like *S. pombe*, which can make excessive amounts of acetaldehyde (Yokotsuka *et al.*, 1993).

Understanding the dynamics of the interaction between two different yeast within a co-culture fermentation is complicated. On a transcriptional level, it has been shown that the non-*Saccharomyces* partner exerts their influence on the fermentative capability and nutrient acquisition of *S. cerevisiae*, as the expression of genes involved in glycolysis are dramatically modulated during a co-culture fermentations (Curiel *et al.*, 2017; Sadoudi *et al.*, 2017; Barbosa *et al.*, 2015; Milanovic *et al.*, 2012).

Regarding the genomics of NSY, a recent instructive review detailed the progress made in sequencing the important members of NSY commonly found in wine (Masneuf-Pomarede *et al.*, 2016). The overwhelming majority of the important wine-related NSYs have at least one member with a whole genome sequenced. As shown for *S. cerevisiae*, the genome sequence of NSYs (especially if multiple members are sequenced) will help untap the molecular underpinnings of their enological features. Since this review, multiple reports were published discussing and comparing the genomes sequenced of important NSYs, including the genomes of *Hanseniaspora* (Guaragnella *et al.*, 2020; Saubin *et al.*, 2020; Chen *et al.*, 2019) and *Starmerella* (Lemos Junior *et al.*, 2018). Genetic modification (GM) would be useful in validating certain gene studies but could also improve the enological properties of a specific NSY. The modification tools for the most common NSY strains are not well-developed as for *S. cerevisiae*, with only a few GM attempts of NSY described in literature, e.g., *T. delbrueckii* (Pacheco *et al.*, 2009) and *Metschnikowia* spp. (Gordon *et al.*, 2019; Nigro *et al.*, 2004). The exception is that of *S. pombe*, a yeast widely used in human disease studies and thus has a sophisticated GM toolbox (Fennessy *et al.*, 2014). As of yet, genetically modified NSYs have not been tested in a laboratory setting or any larger enological setting.

Implementations of coculturing fermentations are costly for a winemaker as two instead of one starter cultures have to be purchased. Also, as with *S. cerevisiae*, there are massive clonal variation in the performance of the same species (Escribano *et al.*, 2018). Even though the literature shows a promising future for coculturing must fermentations, considerable anecdotal evidence suggests difficulties with reproducibility. The dynamic behavior of two (or more) yeast within a fermenting vessel cannot be accurately predicted. Thus, many of these coculturing fermentations are still developed by trial-and-error methods. Nevertheless, their effects on wine are beyond dispute.

Concluding Remarks

As one the world's oldest biotechnological industries, winemaking is steeped in a rich history of tradition and innovation (Jagtap *et al.*, 2017). Despite the fact that wine is an archetypal traditional fermented beverage with strong territorial and socio-cultural connotations, business-savvy winemakers know all too well that continuous product innovation is a vital source of their competitive advantage in the marketplace (Pretorius, 2020). Continuous innovation is a fundamental business principle, which guided the wine industry's ongoing interest in Nature's treasure trove of *Saccharomyces* and non-*Saccharomyces* yeasts and how these yeasts can be further improved or used in combinations to increase the quality of the end-product.

We live in an era of transformative technologies and unprecedented scientific breakthroughs. The opportunity to harness the traditions and wisdom of the distant past and combine that knowledge with innovative technologies, such as biodigital data mining and synthetic genomics, have never been so great as now (Pretorius, 2017, 2020). Wine yeast strain development programs and the application of tailor-made blends of *Saccharomyces* and non-*Saccharomyces* stand to gain enormously from these emerging technologies. Specialized permutations of compatible *Saccharomyces* and non-*Saccharomyces* yeast strains can be differentially combined in multi-starter fermentations depending on the desired outcome from a wine quality perspective. In this way, synergistic wine yeast consortia properties and tap into the unparalleled functional versatility of *Saccharomyces* and non-*Saccharomyces* yeasts. Blending yeast starter-culture consortia for modeling purposes will require an acceleration of the current biodiversity prospecting and the purposeful hunting for non-*Saccharomyces* yeasts in those vineyards and associated wineries.

Introduction

In the last decades, global improvement in living standards has pushed the search for sustainable energy as alternative to the use of non-renewable fossil fuels to meet the energy requirements worldwide. In this context (bio)ethanol, also known as ethyl alcohol or chemically C_2H_5OH , is recognized as the most widely used biofuel in the transportation sector, with a long history as alternative fuel (Guo *et al.*, 2015). Additionally, ethanol is an industrially relevant chemical present in a wide range of products such as solvents, cosmetics, food and beverages, disinfectants, and pharmaceutical preparations (Fig. 1). Microorganisms such as bacteria and yeasts play a key role in bioethanol production by fermenting a wide range of sugars to ethanol. At the industrial level, yeasts are the preferred microorganisms for ethanol production due to their valuable properties regarding ethanol yields, tolerance, productivity, resistance to inhibitors, and their suitability to grow in very simple and inexpensive media (Mohd-Azhar *et al.*, 2017).

In this chapter, we focus on the process of ethanol production by yeasts and we highlight the most relevant physical, chemical and molecular factors affecting ethanol production and tolerance.

Ethanol Production by Yeasts During the Fermentation Process

The term “fermentation” derives from the Latin word *fervere*, which means to boil, to be in turmoil. It can be defined as a metabolic process in which the biochemical transformation of organic compounds, such as carbohydrates, takes place with the aid of enzymes to obtain cellular energy. Because it does not require oxygen, fermentation is classified as an anaerobic process. There are different types of fermentation, such as ethanol fermentation, in which one glucose molecule is converted into two ethanol molecules; lactic acid fermentation, in which one molecule of any six-carbon sugar is converted to two lactic acid molecules; and others, including the fermentative hydrogen production (Narayanan *et al.*, 2004; Reddy *et al.*, 2008; Wang and

Fig. 1 Schematic representation of the main industrial applications of ethanol.

Fig. 2 Glycolysis and ethanol fermentation pathways. ATP = Adenosine triphosphate, NADH = nicotinamide adenine dinucleotide, TCA = tricarboxylic acid, OXPHOS = oxidative phosphorylation.

Wan, 2009). In this chapter, we focus on the ethanol fermentation process carried out by both *Saccharomyces* and non-*Saccharomyces* yeasts due to its relevance for many industrial applications.

Bioethanol production is based on the ability of yeasts to catabolize six-carbon molecules such as glucose, fructose, mannose, or galactose into ethanol, a two-carbon compound. The biosynthetic reactions by which yeasts convert glucose to ethanol are known as the Embden-Meyerhof-Parnas (glycolytic) pathway followed by fermentation (van Dijken and Scheffers, 1986). The glycolytic pathway occurs in the cytoplasm. Cells produce adenosine 5'-triphosphate (ATP) and nicotinamide adenine dinucleotide (NADH) without the involvement of molecular oxygen. First, glucose is phosphorylated and one ATP molecule is consumed to obtain glucose-6-phosphate, which is then converted to fructose-6-phosphate. Fructose-6-phosphate is subsequently transformed to fructose-1,6-biphosphate with the consumption of one ATP molecule, and the resulting fructose-1,6-biphosphate is transformed into two three-carbon sugar compounds, glyceraldehyde-3-phosphate and dihydroxyacetone phosphate (Fig. 2). In the downstream reactions, the three-carbon sugars are transformed into pyruvate, each yielding two ATPs and one NADH. Pyruvate is located at the branch-point between respiratory dissimilation of sugars and alcoholic fermentation. In most organisms, pyruvate is transported into mitochondria, where it is converted into acetyl CoA and CO₂. The acetyl CoA is completely oxidized in the presence of O₂ into CO₂ and H₂O in the so called respiration process (Barnett, 1976; Joseph-Horne *et al.*, 2001). However, in many yeasts respiration only occurs under aerobic conditions when glucose levels are kept very low. In contrast, fermentation occurs in the mitochondria despite the presence of oxygen, represses respiration, and can use alternative carbon sources in a phenomenon known as "Crabtree effect" (de Deken, 1966). In these yeasts, pyruvate is decarboxylated to acetaldehyde and CO₂ by pyruvate decarboxylase (Hohmann and Cederberg, 1990). Acetaldehyde is then reduced to ethanol by the activity of alcohol dehydrogenase, resulting in the re-oxidation of NADH to NAD⁺ (Fig. 2). Yeasts produce alcohol because the production of ATP is faster in fermentation compared to respiration. Besides, yeasts need to maintain the redox balance when consuming sugars under anaerobic conditions, so the NADH/NAD⁺ ratio in fermentation is unaltered. Additionally, fermentation offers the advantage of ethanol production, which acts as an inhibitor of competing microbes that are not ethanol tolerant (Piskur *et al.*, 2006). Thus, the ability to survive and proliferate in high ethanol levels during fermentation is both ecologically important and industrially relevant trait of yeast cells (Voordeckers *et al.*, 2015).

Ethanol Fermentation by *Saccharomyces* Yeasts

Among the yeasts carrying out alcoholic fermentation, species of the genus *Saccharomyces* play a key role in the ethanol fermentation process (Belloch *et al.*, 2008). *Saccharomyces* yeasts acquired their competitive advantage in rich environments by

gaining the ability to produce and tolerate large amounts of ethanol (Tables 1 and 2), as well as through their ability to grow in both anaerobic and aerobic conditions (Sicard and Legras, 2011). The baker's yeast *S. cerevisiae*, a Generally Regarded as Safe (GRAS) microorganism, is a well-studied model system in biochemistry, cell biology, classical genetics, and molecular biology (Duina et al., 2014), and has become the microorganism of choice for the industrial production of ethanol (Zaldivar et al., 2001). *S. cerevisiae* is one of the most fermentative-prone microbial species, producing ethanol even in the presence of excess oxygen. It shows fast rates of sugar consumption and ethanol production, tolerates high levels of ethanol and organic acids, and is also one of the few yeast species that can grow under strictly anaerobic conditions (Albergaria and Arneborg, 2016). All these characteristics allow this yeast to be considered the agent of wine, bread, ale beer, and palm and sake fermentations (Lodolo et al., 2008).

Besides *S. cerevisiae*, other *Saccharomyces* species used in fermentation include *Saccharomyces bayanus* (syn. *Saccharomyces uvarum*), a cryophilic yeast isolated from wine and cider fermentations (Naumov et al., 2001). It is involved in lager beer fermentation and in wine making for its ability to ferment at lower temperatures, making it popular for white wine production. Moreover, *S. bayanus* contributed with the aroma attributes of Chardonnay juice and has been used in the fermentation of red grape varieties (Blazquez-Rojas et al., 2012; Eglinton et al., 2000). Another interesting species of this group is *Saccharomyces paradoxus*, the closest known relative of *S. cerevisiae* (Koufopanou et al., 2006). *S. paradoxus* has been described as the main yeast in Croatian wines (Redžepović et al., 2002) and provides an alternative approach to Chardonnay fermentation (Orlic et al., 2007). Additional *Saccharomyces* species are *Saccharomyces cariocanus*, *Saccharomyces mikatae* and *Saccharomyces kudriavzevii*, which have been found in natural environments (Naumov et al., 2000), but are not present in fermentative environments. However, hybridizations have allowed the generation of efficient ethanol-producing strains, such as *S. cerevisiae* x *S. mikatae* hybrids, which show similar ethanol levels to the *S. cerevisiae* parent-made wines (Bellon et al., 2013). Other examples are *S. cerevisiae* x *S. kudriavzevii* hybrids, which acquired properties of both parental strains, such as good alcohol and glucose tolerance, fast fermentation performance, better adaptation to low and intermediate temperatures, and higher production of glycerol and aromatic compounds (Belloch et al., 2008). Another hybrid, *Saccharomyces pastorianus* (syn. *Saccharomyces carlsbergensis*), a natural hybrid of *S. bayanus* and *S. cerevisiae* is involved in the production of lager beer being responsible for 90% of the beer market (Miller et al., 2012).

Fermentation by Non-*Saccharomyces* Yeasts

While *S. cerevisiae* is undoubtedly the organism of choice for industrial production of ethanol, non-*Saccharomyces* yeasts, a group of genetically diverse microorganisms, also present high potential during the fermentation process (Tables 1 and 2). Non-*Saccharomyces* yeasts were initially considered as "wild" or "spoilage" yeasts, because they were often isolated from stuck or sluggish fermentations, or wines with anomalous analytical and sensorial profiles. However, nowadays the importance of non-*Saccharomyces* yeasts in spontaneous fermentation has been demonstrated since they contribute positively to the definition of the sensory quality of alcoholic beverages (Belda et al., 2017). Highly diverse yeast populations, mainly belonging to the genera *Pichia*, *Candida*, *Hanseniaspora*, *Metschnikowia*, *Issatchenkia* and *Kluyveromyces* are often described in the initial stages of fermentation (Zott et al., 2008), while sometimes other yeast species such as *Torulaspora*, *Saccharomycodes*, *Dekkera*, *Zygosaccharomyces* and *Schizosaccharomyces*, are also observed (Fleet, 2008).

It has been shown that non-*Saccharomyces* strains can be detected (ranging from 10^3 – 10^5 cells/mL) throughout wine fermentation (Jolly et al., 2003). However, most of them are soon overtaken by the strongly fermentative *S. cerevisiae* strains until the process ends (Albergaria and Arneborg, 2016). Non-*Saccharomyces* yeasts exert their metabolic activity contributing to the fermentative process (Pretorius, 2000) by bringing some specific enological characteristics. They produce high levels of aromatic compounds such as esters, higher alcohols and fatty acids, which contribute to the sensory quality of alcoholic beverages (Viana et al., 2008). Furthermore, they can ferment at low oxygen concentrations, allowing the increase of biomass and decrease in ethanol yields, a strategy that can be used to reduce the ethanol content of wines produced in co-culture with *S. cerevisiae* (Contreras et al., 2014). Thus, to improve the chemical composition and sensory properties of wine, the use of non-*Saccharomyces* together with *Saccharomyces* strains as part of mixed and multistarter fermentations has been proposed as an alternative to spontaneous fermentation (Romano et al., 2003).

Several non-*Saccharomyces* yeasts have already been used in fermentation procedures. For example, wines of the grape varieties Sauvignon Blanc, Chenin Blanc and Muscat d'Alexandrie have been obtained by sequential fermentation with *Metschnikowia pulcherrima* (anamorph *Caesalpinia pulcherrima*) and *S. cerevisiae*, showing higher quality scores than control wines obtained by fermentation with *S. cerevisiae* alone (Varela et al., 2016). *Hanseniaspora* species, such as *Hanseniaspora uvarum* (anamorph *Kloeckera apiculata*), generally show low fermentative capacity, but are important in the production of wine volatile compounds. *Hanseniaspora vineae* (formerly *Hanseniaspora osmophila*) and *Hanseniaspora guilliermondii* have been reported to produce increased amounts of 2-phenyl-ethyl acetate associated with "rose", "honey", "fruity" and "flowery" aromas (Viana et al., 2011). Other non-*Saccharomyces* species such as *Torulaspora delbrueckii* (teleomorph of *Candida colliculosa*), co-inoculated with *S. cerevisiae*, are used for the production of Sauvignon Blanc and Chenin Blanc wines (Jolly et al., 2003). The co-inoculation of *T. delbrueckii* and *S. cerevisiae* simultaneously and/or sequentially also increased aroma in Vino Santo and Amarone wines (Azzolini et al., 2015). *Schizosaccharomyces pombe* was used in mixed fermentations with *S. cerevisiae* to remove malic acid and total acidity in Airen grape juice (Benito et al., 2012) and has also been used to partially remove gluconic acid after fermentation of Pedro Ximenez wines (Peinado et al., 2004). Fermentation of Sangiovese grape must with *Lachancea thermotolerans* (*Kluyveromyces thermotolerans*)/*S. cerevisiae* produced wines that scored higher in "spicy" and "acidity" attributes than *S. cerevisiae* wines (Gobbi et al., 2013). In addition, *Kluyveromyces marxianus* is involved in the production of the traditional Mexican spirits tequila and mezcal using *Agave tequilana* (Flores et al., 2013; Lopez-Alvarez et al., 2012).

Table 1 Ethanol production of *Saccharomyces* and non-*Saccharomyces* yeasts

Strain	Substrate (concentration, g/L)	Time (h)	Temperature (°C)	Ethanol production (g/L)	References
<i>Saccharomyces</i>					
<i>S. cerevisiae</i>	Glucose (50–200)	18–94	30	5.1–91.8	Vallet <i>et al.</i> (1996)

Industrial Process for Bioethanol Production

The process of bioethanol production by yeasts largely depends on the feedstock used, which is normally pretreated to facilitate the subsequent processes. There are four methods currently applied during pretreatment, which are physical (i.e., milling), chemical (i.e., acid/alkaline hydrolysis), biological, and physicochemical (i.e., steam) (Mohd-Azhar *et al.*, 2017). After pretreatment, hydrolysis takes place. During hydrolysis, feedstocks are broken down into fermentable sugars through two possible methods: (1) acid hydrolysis, which requires high temperatures and low pH, generating inhibitory by-products; and/or (2) enzymatic hydrolysis, which is performed at less severe conditions and has the potential for total conversion of biomass to

glucose (Khawla *et al.*, 2014). After hydrolysis, the fermentation process follows (see Section “Ethanol Production by Yeasts during the Fermentation Process”). Fermentation can be performed in batch, where substrates are only provided at the beginning of the process without changing the medium; repeated batch, which involves repeated cycles of fermentation by re-inoculating the cells from one batch fermentation broth to the next batch; continuous mode, carried out by constantly adding substrates, culture medium and nutrients; and fed-batch, which is a combination of batch and continuous mode (Mohd-Azhar *et al.*, 2017).

Several factors affect the production of bioethanol, such as temperature, sugar concentration, pH, dissolved O₂, and fermentation time, which are carefully regulated throughout the fermentation process (Fakruddin *et al.*, 2012; Mohd-Azhar *et al.*, 2017). Temperature directly affects yeast's growth rate. The ideal temperature ranges from 20 to 35°C, and higher temperatures may lead to the generation of heat stress and lower ethanol titers. Initial sugar concentration has also been considered as a key factor in ethanol production, since an increase of sugar concentration directly correlates with an increase in the fermentation rate. However, sugar excess can cause steady fermentation rates. pH also affects ethanol production since it directly affects yeast growth. The optimum pH in fermentation ranges from pH 4.0–6.0, and higher pH is often associated with reduced ethanol yields. Aeration was also shown to influence fermentation. A high agitation rate positively correlates with high ethanol production by increasing the amount of sugar consumption and reducing growth inhibition by ethanol (see below). Finally, the fermentation time also affects ethanol yields. Short fermentation times result in partial fermentation due to inadequate growth of microorganisms, whereas long fermentation times may have toxic effects on microbial growth, particularly in the batch mode due to ethanol accumulation (Fakruddin *et al.*, 2012; Mohd-Azhar *et al.*, 2017).

Molecular Basis of Fermentation-Associated Stress

During fermentation, yeast cells are exposed to several stresses, including osmotic, ethanol, heat, and oxidative stress. Initially, cells deal with osmotic stress due to high sugar concentrations, while at the end of the fermentation process high ethanol concentration is the most important stress that inhibits yeast growth and metabolism, leading to the end of ethanol production (Auesukaree, 2017). The cellular response to fermentation-associated stresses involves interplay of several hundreds of genes in complex networks. As an example of this, Rossignol and collaborators have reported a change in the expression of more than 2,000 genes during *S. cerevisiae* fermentation (Rossignol *et al.*, 2003).

To deal with the different fermentation-associated stresses, yeast cells undergo several genetic responses. The osmo-regulatory response involves the activation of the high osmolarity glycerol (HOG) pathway (Saito and Posas, 2012). When yeast cells are exposed to hyperosmotic shock, the HOG pathway is stimulated and the stress-activated protein (SAP) kinase Hog1 is phosphorylated (Tatebayashi *et al.*, 2020). Activated Hog1 regulates the activities of the transcriptional activators Hot1, Smp1, Msn1, Msn2, and Msn4, and the repressor Sko1. These transcription factors bind to the so called stress response elements (STREs) (Saito and Posas, 2012). The STREs also mediate induction of transcription by heat shock, nitrogen starvation and oxidative stress (Schüller *et al.*, 1994) leading to the transcriptional activation of downstream genes related with a broad range of functional categories, including glycerol synthesis, protein biosynthesis, amino acid metabolism, nucleotide metabolism, transport, cell cycle and growth, lipid metabolism, fatty acid and ergosterol metabolism, membrane and cell wall organization, and proline and tryptophan biosynthesis (Ma and Liu, 2010).

Other groups of osmo-inducible genes include those involved in the protection against oxidative damage and protein denaturation, such as genes encoding antioxidants (*CTT1*, *GRE3*, *TRX2*, *TTR1*) and chaperones (*HSP12*, *HSP26*, *HSP42*, *HSP70*, *HSP90*, *HSP104*) (Auesukaree, 2017). Heat shock proteins (HSPs) are produced together with compatible solutes such as trehalose (Verghese *et al.*, 2012) which also plays a role in preventing protein denaturation and aggregation through its function as a protein stabilizer. It binds to unfolded proteins to maintain them in a partially-folded state until being refolded by molecular chaperones (Singer and Lindquist, 1998). The expression of trehalose metabolism-related genes including *TPS1*, *TPS2*, and *NTH1*, is rapidly up-regulated under heat stress, resulting in an increase of intracellular trehalose levels (Kitichantaropas *et al.*, 2016). In agreement, the *TPS2* gene has been shown to be required for tolerances to heat, oxidative, osmotic, and ethanol stresses (Auesukaree *et al.*, 2009).

At the end of the fermentative phase, a transient growth arrest (diauxic shift) occurs in yeasts, in which major changes in gene expression enable cells to grow throughout respiration. Using the ethanol accumulated during the fermentative growth induces the production of reactive oxygen species (ROS) (Du and Takagi, 2007). In order to deal with ROS production, the superoxide dismutase (SOD) converts superoxide anion into hydrogen peroxide, which is then reduced to water and oxygen by catalase, glutathione peroxidase and thioredoxin peroxidase (Culotta *et al.*, 2006). Yeast cells have three glutathione peroxidases, Gpx1, Gpx2, and Gpx3, which reduce phospholipid hydroperoxides, suggesting their role in protecting membrane lipids from peroxidation (Avery and Avery, 2001).

Many other genes associated with oxidative stress are upregulated under the control of Yap1p and Skn7 transcription factors. Yap1p and Skn7 coordinately control the transcription of oxidative stress-responsive genes including *SOD1* and *SOD2*, the thioredoxin encoding gene *TRX2*, the thioredoxin reductase-encoding gene *TRR1*, the peroxiredoxins encoding genes *TSA1* and *AHP1*, as well as *GPX2*, which encodes a glutathione peroxidase (Morano *et al.*, 2012).

Ethanol Stress and Tolerance

During fermentation, high ethanol concentrations cause an increase in fluidity and permeability, and consequential decrease in the yeast membrane integrity, which induces an increased passive influx of ions across the membrane triggering cytosolic acidification

(Charoenbhakdi *et al.*, 2016). Consequently, yeast cells show an elevation of H^+ ATPase activity in plasma membrane (Fujita *et al.*, 2006) due to up-regulation of *PMA1* and *PMA2* genes (Fernandes and Sa-Correia, 2003). Additionally, to maintain membrane integrity and to modify membrane fluidity, some studies have identified changes associated to membrane composition, including changes in the balance of ergosterol and unsaturated fatty acids (UFAs). The predominant mono-UFAs are the palmitoleic and oleic acids, which are obtained by the desaturation of the saturated palmitic and stearic acids, respectively. This reaction is catalyzed by a membrane desaturase encoded by the gene *OLE1* (Ma and Liu, 2010), which is up-regulated during fermentation.

High ergosterol content in yeasts is associated with higher ethanol tolerance (del Castillo-Agudo, 1992). Deletion mutants of *ERG2*, *ERG3*, *ERG5*, *ERG6*, *ERG24*, and *ERG28* involved in ergosterol biosynthesis showed defective growth of yeast cells under ethanol stress (Auesukaree *et al.*, 2009). Furthermore, the cell wall integrity pathway has been reported to play an important role in controlling the transcriptional adaptive response to cell wall stress, leading to a remodeling of the cell wall architecture in order to improve its resistance (Orlean, 2012). The *BCK1* and *SLT2* genes encoding mitogen activated protein (MAP)3K and MAPK, respectively, have also been reported to be essential for ethanol tolerance. Upon ethanol exposure, the expression of specific cell wall-remodeling genes, including *FKS2*, *CRH1*, and *PIR3* (encoding α -1,3-glucan synthase, chitin transglycosylase, and O-glycosylated cell wall protein, respectively) are induced (Udom *et al.*, 2019).

On the other hand, trehalose accumulation has been reported to be crucial for improved yeast growth under ethanol stressing conditions by alleviating ethanol-induced membrane permeabilization (Mansure *et al.*, 1994). The expression of trehalose metabolism-related genes such as *TPS1*, *TPS2*, and *NTH1* are up-regulated upon ethanol exposure. Trehalose is also involved in the close interplay with HSPs in stabilizing protein structures through its functions in protein binding and reduction of water activity (Jain and Roy, 2009).

Some amino acids, including proline, tryptophan and arginine, also show protective effect against ethanol stress. The expression of the *PUT4* gene encoding a high affinity proline transporter was strongly induced upon ethanol exposure (Kaino and Takagi, 2008). Proline has been shown to play a role in stabilizing proteins and membranes, and in inhibiting protein aggregation during refolding (Ignatova and Gierasch, 2006), suggesting a role in protecting yeast cells against the adverse effects of ethanol on proteins and membranes. In addition, proline has the ability to scavenge several ROS including hydroxy radicals and superoxide anions (Kaul *et al.*, 2008). In the case of tryptophan, the deletion of genes encoding tryptophan biosynthesis-related enzymes, i.e., *TRP1*, *TRP2*, *TRP3*, *TRP4* and *TRP5*, resulted in hypersensitivity to ethanol stress, whereas the overexpression of these genes, especially *TRP1* and *TRP5*, and the tryptophan permease-encoding gene *TAT2*, increased ethanol tolerance after tryptophan supplementation (Yoshikawa *et al.*, 2009). Arginine has also been reported to have a protective effect against ethanol-induced damage on cell wall, plasma membrane and intracellular organelles, possibly due to its role in inhibiting ROS generation (Cheng *et al.*, 2016). Together with the up-regulated genes described above, many other genes have been reported to be down-regulated during ethanol tolerance (Chandler *et al.*, 2004), indicating significant remodeling processes in response to ethanol stress.

Therefore, and despite extensive studies, ethanol tolerance is a complex, polygenic trait influenced by multiple alleles that may show complex interactions and may differ between strains (Snoek *et al.*, 2016). A better understanding of the genetic mechanisms underlying stress tolerance will contribute to generate strains for efficient ethanol fermentation and industrially optimized processes.

Yeast Improvement for Higher Ethanol Production and Tolerance

The main problems associated with the production of ethanol during the fermentation process is alcohol toxicity and growth inhibition of yeast cells, resulting in low alcohol titers in the fermentation broth (Jia *et al.*, 2010). In order to overcome these problems, several approaches have been applied, which include both the classical (non-GMO) optimization and the genetic engineering of yeasts for a higher ethanol production and tolerance.

Classical (Non-GMO) Optimization of Yeasts

Evolutionary engineering

A successful way to obtain strains with increased ethanol production and tolerance is evolutionary engineering, also referred to as adaptive, directed, or experimental evolution. It relies on the basic principles of (natural and/or induced) genetic variation and subsequent strain selection. Basically, a population of cells is grown under continuous selection for the phenotype of interest for many generations. Over time, random mutants will arise and these mutants will be selected for their improved phenotype (Steensels *et al.*, 2014). Strategies based on adaptive evolution are attractive, since they generate improved non-GMO strains that can be used in the industry in the short-term (Cadiere *et al.*, 2011) without going through all the legislation and restrictions associated to GMOs. Some *S. cerevisiae* strains obtained by this technique showed increased ethanol production and tolerance, and higher osmotic and temperature tolerance than their parental strains under laboratory, pilot-scale and industrial fermentation conditions (Basso *et al.*, 2008; Cadiere *et al.*, 2011; Chen and Xu, 2014). Sonderegger and collaborators reported *S. cerevisiae* mutants with up to 19% more ethanol production than the parental strain (Sonderegger and Sauer, 2003), and serial *S. cerevisiae* batch cultures increased the production from 2.5% to 10% (v/v) ethanol compared to parental strain-derived cultures (Dinh *et al.*, 2008).

UV and chemical mutagenesis

In addition to evolutionary engineering, random mutagenesis has also been widely applied to obtain mutants with improved characteristics. Among the classical methods, physical mutagens such as ultraviolet (UV) radiation and chemical agents, including N-methyl-N'-nitro-N nitrosoguanidine (NTG) and ethyl methane sulfonate (EMS), have been shown to be efficient to obtain strains with improved biotechnological properties (Parekh *et al.*, 2000). Studies have described the use of UV to improve ethanol production, tolerance and yield in yeasts, especially in *S. cerevisiae* (Revin *et al.*, 2018). Furthermore, some mutants have shown an increase of osmotolerance and improvement of thermotolerance compared to the wild type (Unaldi *et al.*, 2002). As examples, *Candida shehatae* and *Pichia stipitis* mutants obtained by UV mutagenesis showed better fermentation of xylose and glucose than the parental strain (Li *et al.*, 2012; Watanabe *et al.*, 2011), whereas irradiation of *K. marxianus* produced mutants with higher ethanol yield (0.51 g ethanol/g glucose, and 0.48 g ethanol/g galacturonic acid) than the wild type (0.43 g ethanol/g glucose, and 0.34 g ethanol/g galacturonic acid) at 46°C (Hughes *et al.*, 2013). EMS has been used to obtain *S. cerevisiae* mutants with a production of bioethanol 17.3% higher than the wild type (Mobini-Dehkordi *et al.*, 2008), and the UV irradiation followed by NTG mutagenesis allowed obtaining *K. marxianus* strains with 11% (v/v) of ethanol tolerance compared to the 8% (v/v) of the corresponding parental strain (Pang *et al.*, 2010).

Protoplast fusion

Another non-GMO technique used to improve alcohol productivity in yeasts is protoplast fusion (Steensels *et al.*, 2014). It involves the generation of new strains by allowing recombination between genomes of different parental strains, followed by selection of the cells showing the desired traits (Xin *et al.*, 2020). Using this technique, interspecific or even intergeneric crosses can be obtained. Since meiosis is not required, protoplast fusion can be used to increase the ploidy of the strains, which in some cases increases productivity (Attfield and Bell, 2003). Protoplast fusion is an important tool for the improvement of industrial yeast strains. For example, improvement has been reported for the fusion between the strain *S. cerevisiae* Q, frequently used as beer producer, with *S. cerevisiae* L. The Q/L fusant shows higher ethanol tolerance (14% v/v) than the strain Q (10% v/v) (Xin *et al.*, 2020). Other examples include protoplast fusion of *S. cerevisiae* with *Candida shehatae* followed by UV mutagenesis, resulting in a significant increase in ethanol production at 42°C, with a 90% fermentation efficiency (Pasha *et al.*, 2007). Protoplast fusion between *S. cerevisiae* and *K. marxianus* enhanced ethanol production and temperature tolerance using cheese industry waste (whey) as substrate (Ramasamy *et al.*, 2010). Although protoplast fusion offers great advantages, a strong disadvantage is that many of the hybrids are mitotically unstable and chromosomal loss or dissociation often occurs (Attfield and Bell, 2003).

Genome shuffling

Genome shuffling is also used to improve complex phenotypes in a fast and relatively easy manner (Zhang *et al.*, 2002). By applying repeated rounds of genetic recombination (either by protoplast fusion or mass mating) genome shuffling aims to combine different mutations in the same cell, leading to additive or synergistic effects (Santos and Stephanopoulos, 2008). Frequently, mutants generated by classical methods (UV or chemical mutagenesis) are screened for the phenotype of interest, and cells showing phenotypic improvement are used as a starting population for multiple rounds of genome shuffling. As examples, *S. cerevisiae* mutants generated by EMS or UV mutagenesis followed by genome shuffling showed remarkably enhanced tolerance to ethanol and osmolarity, increased metabolic rate, and increased ethanol yield compared to the wild type (Shi *et al.*, 2009). Similarly, after four rounds of genome shuffling, *C. krusei* improved its ethanol tolerance and production (Wei *et al.*, 2008).

Genetic Engineering of Yeasts

Although non-GMO techniques are preferred from an industrial point of view, non-GMO techniques are often limited to phenotypes that allow efficient selection and may involve a risk of improving one trait at the expense of others. In this context, directed genome manipulation offers a greater potential for the generation of strains with improved characteristics with no (or very few) side effects. Genetic engineering for yeast improvement in the context of ethanol fermentation comprises the manipulation of individual genes or metabolic pathways to increase the rate of sugar conversions to ethanol and ethanol tolerance.

Among the different molecular alternatives available, gene transfer, overexpression and/or gene deletions are the most applied approaches for the rational manipulation of yeast strains aiming at higher ethanol production and tolerance. Regarding ethanol production, deletion of *GPD1* and *GPD2*, two abundant NAD-dependent glycerol-3-phosphate dehydrogenases involved in glycerol synthesis in *S. cerevisiae*, increased ethanol production. Mutants *gpd1Δ* and *gpd2Δ* produced 0.456 and 0.478 g ethanol/g glucose, respectively, compared to the parental strain which produced 0.399 g ethanol/g glucose (Guo *et al.*, 2009). Deletion of *FPS*, which encodes a glycerol channel protein, alone or in combination with *GPD2* and/or *GPD1*, and together with the overexpression of the glutamate synthase-encoding gene *GLN1* and the glucose transporter *GLT-1* also significantly increased ethanol production (Cao *et al.*, 2010; Xiong *et al.*, 2014). Additionally, transfer of the glucoamylase gene of the zygomycete fungus *Rhizopus oryzae* to *S. cerevisiae* was reported to increase ethanol production up to 5% in this model yeast (Yang *et al.*, 2011).

The introduction of more precise genome editing techniques, such as Clustered Regularly Interspaced Short Palindromic Repeats-associated protein-9 nuclease (CRISPR/Cas9) (Doudna and Charpentier, 2014), has greatly improved the efficiency of traditional genetic engineering of yeast. For instance, the (over)expression of the cellulase-encoding gene *sestc*, isolated from the snail *Ampullaria gigas* Spix, under the regulation of the basidiomycete fungus *Agaricus bisporus* glyceraldehyde-3-phosphatedehydrogenase (*gpd*) promoter

was achieved by CRISPR/Cas9 in *S. cerevisiae*. The resulting mutant showed 37.7-fold higher ethanol production than that of the wild type when using orange peel as substrate (Yang *et al.*, 2018). Besides, the disruption of the alcohol dehydrogenase (*ADH2*) gene by CRISPR/Cas9 allowed the introduction of a frameshift mutation in the *ADH2* locus resulting in *S. cerevisiae* strains in which ethanol yield improved up to 74.7% compared to the native strain (Xue *et al.*, 2018).

It is now generally accepted that most cellular phenotypes are multigenic traits. As a result, engineering a desired phenotype would be enormously facilitated by simultaneous multiple gene modifications (Alper and Stephanopoulos, 2007). For this, global Transcription Machinery Engineering (gTME) provides an option for multiple gene manipulation by randomly introducing mutated copies of global transcriptional factors, which control the transcription of a large set of genes (Alper *et al.*, 2006). Through mutagenesis (via error-prone PCR mutations), gTME allows for global perturbations of the transcriptome, so that improved phenotypes can be elicited quickly and effectively (Li *et al.*, 2018). Through gTME, a *S. cerevisiae* strain with three separate mutations in the *SPT15* gene, which encodes the TATA-binding protein, in one component of the RNA polymerase II and in the transcription factor D (TFIID) complex, was obtained. In the mutant, the transcription pattern of hundreds of genes changed and the strain produced 69% more ethanol than the wild type (Alper *et al.*, 2006). Xue *et al.* produced *S. cerevisiae* mutants from a wild type wine yeast, and the mutations in the *SPT8* (suppressor of ty insertions 8) gene, resulted in 8.9% higher ethanol tolerance and 10.8% higher ethanol production compared to the wild type (Xue *et al.*, 2019).

Regarding ethanol tolerance, it is important to highlight that the genetic basis of stress tolerance in yeast cells is very complex, and manipulation at the molecular level to improve stress tolerance still faces many difficulties (Zhao and Bai, 2009). Despite this, several examples demonstrated the successful improvement of yeast tolerance to high ethanol concentrations. For instance, deletion and/or the inactivation of the vacuolar acid trehalase (*ATH1*) gene in *S. cerevisiae* caused high survival rates under various stresses, including ethanol (Jung and Park, 2005).

Conclusions and Future Perspectives

Since the beginning of recorded history, a strong relationship between humans and ethanol has been developed, likely due to its presence in wine and many beverages, and due to its industrial relevance. Yeasts are the organisms of choice to produce ethanol at the industrial level, and strain improvement for high ethanol production and tolerance is of great interest to the scientific community and the industry.

Despite both classical optimization methods and genetic engineering tools have allowed the improvement of yeasts for a more efficient ethanol fermentation process, demands for increased productivity, wider substrate range utilization, as well as changes in consumer preferences lead to a greater interest in further improving the currently available industrial strains. In this context, there is an urgent need to continue exploring the genetic capacity of various natural and/or industrial strains for a better understanding of the ethanol fermentation process, and the physiological and biochemical basis of yeast stress tolerance. Finally, the use of different omics data (proteomics, transcriptomics and metabolomics) together with the implementation of new genetic manipulation techniques and synthetic biology approaches might aid in the development of robust yeast strains for bioethanol production.

The Biosynthesis of Fungal Secondary Metabolites: From Fundamentals to Biotechnological Applications

Olga Mosunova, Jorge C Navarro-Muñoz, and Jérôme Collemare, Westerdijk Fungal Biodiversity Institute, Utrecht, The Netherlands

© 2021 Elsevier Inc. All rights reserved.

Introduction

Secondary metabolites (SMs) are natural products synthesized mainly by bacteria, fungi and plants. They are molecules of low molecular weight with diverse chemical structures and biological activities. The name secondary metabolite originates from the initial observation that their production is not necessary for the growth and reproduction of organisms, in contrast to primary metabolites which include lipids, amino acids, carbohydrates and nucleic acids. However, SMs are far from being secondary and the term “specialized metabolites” is emerging to describe them. It is now accepted that SMs play key roles in the survival of the organisms that produce them because SMs determine interactions within their environment. Nowadays, SM production is a major research field for organic chemists, molecular biologists and bioinformaticians alike. In this review, we will focus on SMs produced by fungi to introduce the fundamental concepts of their biosynthesis, present how the genomics era has impacted the study of fungal SMs, and report the biotechnological tools that have been developed to engineer SM biosynthetic pathways.

Fungi Produce Bioactive Secondary Metabolites That Impact Human Societies

Fungal Secondary Metabolites in Human Daily Life

Fungal SMs have impacted human societies both positively and negatively since ancient times. The episode known as Saint Anthony's fire in 1039 was an outbreak of ergotism, a disease caused by the consumption of rye that we know now was infected by the fungus *Claviceps purpurea* (van Dongen and de Groot, 1995). This disease is actually caused by SMs called ergot alkaloids that are secreted by the fungus. Many other so-called mycotoxins have been reported and their presence in food and feed is strictly regulated and monitored. The most frequently encountered mycotoxins worldwide are produced by *Fusarium* species on cereals and include deoxynivalenol (DON), fumonisin and zearalenone (Biomim mycotoxin survey see “Relevant Websites Section”). Aflatoxins produced by *Aspergillus* species are also an important threat, which are famous to have caused in England the death of 100,000 turkeys that consumed contaminated peanut meal (Richard, 2008).

Although some fungal SMs are mycotoxins, many others exhibit beneficial activities to humans. Hundreds of fungal species, mostly basidiomycetous edible mushroom-forming species, have been used in traditional Chinese medicine for thousands of years. Their beneficial properties are linked to the production of mixtures of SMs with diverse biological activities, for example against cancer, diabetes and cardiovascular diseases (Hyde *et al.*, 2019). In the Western world, fungal SMs have revolutionized modern medicine more than once (Fig. 1). The most famous example is the discovery of the first large-spectrum antibiotic penicillin produced by *Penicillium rubens* (formerly *P. chrysogenum*; (Houbraken *et al.*, 2011)). Penicillin belongs to a family of compounds known as beta-lactams, which still accounts for the largest antibiotic market size. The discovery of cyclosporin A produced by *Tolypocladium inflatum* brought another revolution in the second half of the 20th century: this immunosuppressive SM allowed successful organ transplantation (Colombo and Ammirati, 2011). The statin family of compounds, used as cholesterol-lowering agents, was also discovered in the 1970s and several compounds of fungal origin, like monacolin K, actually represent the largest market of drugs, reaching an annual turn-over circa US\$50 billion (Hyde *et al.*, 2019). Fungal SMs find many other applications in diverse fields, including agriculture (e.g., strobilurin fungicides are all derived from SMs produced by the basidiomycetous mushroom *Strobilurus tenacellus* (Bartlett *et al.*, 2002)) and industry (e.g., *Monascus purpureus* is exploited for the production of red rice powder in Asia because it produces red pigments like rubropunctamine (Mukherjee and Singh, 2011)).

Since the 1990s, the development of natural products into marketed active molecules has entered a so-called discovery void (Fig. 1) because the same molecules of natural origin were rediscovered, which turned companies to redirect their efforts towards chemical synthesis of analogs of existing compounds (Li and Vederas, 2009). Despite having provided key compounds to human societies, the

Fig. 1 Discovery of fungal secondary metabolites with commercial application. Since the end of the 1980s, we have entered a so-called discovery void due to companies stopping the prospection of natural products and investing in chemical synthesis. Since the release of the first genomes of filamentous fungi at the beginning of the 21st century, the genomic era has revived interest in fungal secondary metabolites.

fungal kingdom had been neglected in the search for natural products. But the genomic era promises to bring fungi in the spotlight again, especially to find solutions to the emergence of multi-resistant bacterial and fungal pathogens (Harvey *et al.*, 2015). Academic laboratories and small and medium enterprises have initiated new exploitation of the fungal kingdom for bioactive compounds, and these initiatives represent the beginning of a long-term research effort.

Fungal Secondary Metabolites in Fungal Daily Life

While fungal SMs exhibit biological activities that are useful or detrimental to humans, these activities are most often side effects and do not reflect the biological function for the organisms that produce them. It is now well accepted that SMs have important functions in the interactions between fungi and their environments, especially by contributing to the colonization of specific ecological niches. Fungal pigments like dihydroxynaphthalene (DHN) melanin and cladofulvin provide protection against environmental stresses such as UV light, desiccation and extreme temperatures (Langfelder *et al.*, 2003; Dadachova *et al.*, 2007; Griffiths *et al.*, 2018). Fungal SMs are particularly important for pathogens to establish disease. DHN melanin protects human pathogens from the immune system (Chai *et al.*, 2010; Thywissen *et al.*, 2011), while this SM is required for certain plant pathogens to mechanically penetrate plant tissues (Chumley and Valent, 1990). Toxic SMs are particularly well known to contribute to plant infection. Host-specific toxins (e.g., HC-toxin, AK-toxin) produced by *Cochliobolus* and *Alternaria* species determine their host range by targeting plant cultivars that carry a sensitivity gene (Stergiopoulos *et al.*, 2013). Non-specific toxins are more widely distributed and also contribute to the virulence of many fungi. One of the most studied class of toxins are perylenequinones, photoactive toxins that make *Cercospora nicotianae* pathogenic on tobacco (Choquer *et al.*, 2005; Ebert *et al.*, 2019). More recently, it is becoming clear that SMs produced by plant pathogens play more diverse and subtle roles in virulence which are not straightforward to study (Collemare *et al.*, 2019). Symbiotic fungi also appear to rely on the production of SMs to establish a mutualistic interaction with their hosts. The ectomycorrhizal fungus *Laccaria bicolor* secretes terpenes that were shown to be required for symbiosis establishment (Ditengou *et al.*, 2015), while the symbiont *Epichloë festucae* produces indole alkaloid SMs that protect its ryegrass host from herbivorous animals (Schardl *et al.*, 2013). Such a defensive biological function can be extended to antimicrobial compounds produced by fungi when they compete with other microorganisms living in the same ecological niche (O'Brien and Wright, 2011). This function was recently experimentally proven with bikaverin and beauvericin produced by *Fusarium fujikuroi* against the bacterium *Ralstonia solanacearum* (Spraker *et al.*, 2018) and with lagopodin B produced by *Coprinopsis cinerea* in response to the presence of bacteria (Stöckli *et al.*, 2019).

The Fundamentals of Secondary Metabolite Production in Fungi

A Diversity of Biosynthetic Enzymes

Fungal SMs are classified into a few major chemical classes depending on the precursors (either acyl-coAs, amino acids, or prenyl diphosphates) and enzymes used for their biosynthesis (Keller, 2019). Polyketides, non-ribosomal peptides, terpenes and indole alkaloids are synthesized by core enzymes named polyketides synthases (PKSs), non-ribosomal peptide synthetases (NRPSs), terpene cyclases (TCs) and dimethylallyltryptophan synthases (DMATSs), respectively (Fig. 2 and Fig. 3(A)). These core enzymes are characterized by highly conserved domains that exhibit diverse catalytic activities. TCs and DMATSs are enzymes which are composed of one or two conserved domains (Schmidt-Dannert, 2015). In contrast, PKSs and NRPSs are multidomain mega-enzymes with complex catalytic activities (Fig. 3(A)).

In fungi, two types of PKSs are found: iterative type I PKSs and type III PKSs. Type I PKSs are mega-enzymes with several domains that are used iteratively to elongate the polyketide backbone mostly from acetyl- and malonyl-CoA (Cox, 2007; Herbst *et al.*, 2018). Type I iterative PKSs are further classified into three groups depending on the presence of specific conserved domains (Fig. 3(A)). Non-reducing PKSs (nrPKSs) produce aromatic compounds while reducing (rPKS) and partially reducing (prPKS) enzymes produce reduced polyketides due to the presence of one or several reducing conserved domains (dehydratase (DH), keto-reductase (KR) and enoyl-reductase (ER) domains) (Cox, 2007; Herbst *et al.*, 2018). The release of the polyketide chain from the PKS can be performed through different mechanisms depending on the presence of a final thiol-esterase (TE) or reductase (R) domain (Cox, 2007). Certain PKSs do not carry such a releasing domain and have co-evolved with other enzymes, including beta-lactamases and hydrolases, to release the polyketide chain (Cox, 2007; Griffiths *et al.*, 2016). While progress has been made towards understanding the programming of iterative type I PKSs, predicting the compound they will produce in terms of acyl-CoA specificity, chain length, cyclisation and reduction steps, remains challenging.

Type III PKSs are small enzymes consisting of a single keto-synthase (KS) domain (Fig. 3(A)). They catalyze the iterative condensation of a starter fatty acyl-coA and several extender units, mostly malonyl-CoA (Shimizu *et al.*, 2017). Type III PKSs show considerable flexibility, accepting a wide range of starter unit, from short to long linear or cyclic acyl-coA, resulting in the production of a variety of compounds (Shimizu *et al.*, 2017; Kaneko *et al.*, 2019). Compared to type I PKSs, fungal type III PKSs have been neglected enzymes and more research effort is needed to understand how they function.

NRPSs are large multi-modular enzymes, each module usually consisting of three conserved domains (Fig. 3(A)): adenylation (A; recruits an amino acid), condensation (C; catalyses the peptide bond) and thiolation (T; carries the peptide chain) domains (Singh *et al.*, 2017). Eventually, amino acid epimerization and N-methylation domains can be found within modules

Fig. 2 Diversity of chemical structures observed for fungal secondary metabolites (SMs). Examples of fungal secondary metabolites. (A) polyketides (1) 1,8-dihydroxynaphthalene; (2) aflatoxin B1; (3) fumonisin B; (4) cyperone B1, (B) non-ribosomal peptides (5) penicillin G; (6) beauvericin, (C) hybrid polyketide-peptides (7) monacolin K; (8) cytochalasin A, (D) hybrid peptide-polyketides (9) tenuazonic acid, (E) non-ribosomal peptide-like (10) atromentin; (11) microporphanone, (F) terpenes (12) deoxynivalenol; (13) lagopodin B, (G) indole alkaloids (14) ergotamine, (H) NRPS-independent siderophore (NIS) (15) rhizoferrin, (I) Ribosomally synthesized and post-translationally modified peptides (RiPPs) (16) ustiloxin, and (J) unconventional compounds (17) psilocybin.

(Singh *et al.*, 2017). Often, the NRPS organization ends with a single C domain that is responsible for the release of the peptide chain through cyclisation (Zhang *et al.*, 2016). In many cases, NRPS modules are sequentially used, so that the number and order of the modules determine the length and nature of the peptide. However, some fungal NRPSs are iterative and contain modules that reuse the A domain of another module to incorporate a new amino acid (Schwecke *et al.*, 2006; Yu *et al.*, 2017). Similarly to fungal PKSs, it is possible to classify NRPSs into large phylogenetic groups (Bushley and Turgeon, 2010), but predicting which

Fig. 3 Secondary metabolite (SM) biosynthetic pathways in fungal genomes. (A) Core genes and enzymes involved in the biosynthesis of the SM chemical backbone. The module organization of the core enzymes is shown with the arrangement of conserved domains. SAT: Starter Acyl-carrier protein Transacylase; KS: Keto-Synthase; AT: Acyl-Transferase; PT: Product Template; ACP: Acyl-Carrier Protein; TE: ThioEsterase; CLC: Claisen Cyclase; MT: Methyl Transferase; R: Reductase; DH: DeHydratase; ER: Enoyl Reductase; KR: Keto Reductase; A: Adenylation; T: Thiolation; C: Condensation; E: Epimerization; TC: Terpene Cyclase; SQCY: Squalene Cyclase; PPT: PolyPrenyl transferase; ABBA-PT: Aromatic Prenyl Transferase; SP: Signal Peptide. Two architectures are found for iterative type I non reducing polyketide synthases (PKSs), but both are characterized by the presence of the SAT and PT domains. The brackets indicate that the ACP domain is duplicated in certain enzymes. Type I reducing PKSs are characterized by the presence of at least one of the DH, ER and KR domain. The brackets indicate the domains that are not found in partially reducing PKSs. The most common structure of NRPS-like enzymes is represented, but diverse domains, including ferric reductase, polynucleotidyl transferase ribonuclease H and LPS-induced tumor necrosis alpha factor, linked to a single A domain are also found. Terpene Cyclases (TCs) are classified into different groups according to the conserved domain they harbor. Bifunctional TCs are characterized by the presence of a PPT domain. NRPS-independent siderophore (NIS) synthetases contain a single *lucA_lucC* domain. Ribosomally synthesized and post-translationally modified peptides (RiPPs) are encoded by genes. In many cases, the precursor peptide contains a SP followed by a repetitive sequence, which consists of the core peptide embedded between N- and C-terminal sequences and KR recognition motif for the kexin Golgi protease. (B) The biosynthetic gene cluster organization. Reproduced from Bushley, K.E., Turgeon, B.G., 2010. Phylogenomics reveals subfamilies of fungal nonribosomal peptide synthetases and their evolutionary relationships. *BMC Evolutionary Biology* 10 (1), 26. doi:10.1186/1471-2148-10-26.

amino acids are incorporated remains difficult. A recent study revealed that the activity of NRPS modules also depends on the presence of other surrounding modules (Degen *et al.*, 2019), making these predictions even more uncertain.

Hybrid enzymes between PKSs and NRPSs are also commonly found in fungi, either as PKS-NRPS or NRPS-PKS hybrid enzymes (Fig. 3(A)). The former consists of an rPKS fused to a single NRPS module and a final releasing domain, leading to the production of a polyketide which contains a single amino acid (Fisch, 2013). These enzymes are notably known for the production of cytochalasins, which are inhibitors of actin polymerization (Skellam, 2017). Statins are produced by hybrid PKS-NRPSs that are truncated and have lost the A and T domains, consistent with the absence of an amino acid in the statin chemical structure (Boettger *et al.*, 2012). Hybrid NRPS-PKSs are less widespread and thus less studied. The only two characterized fungal NRPS-PKSs either carry a single NRPS module upstream of a KS domain or an A-T module upstream of a prPKS, and they are respectively responsible for the production of tenuazonic acid in the rice pathogen *Pyricularia oryzae* (Yun *et al.*, 2015), and of swainsonine in the insect pathogen *Metarhizium robertsii* (Cook *et al.*, 2017).

Several other classes have been less studied in fungi (Fig. 2 and Fig. 3(A)). NRPS-like enzymes consist of a single A-T module linked to various extra domains, including thioester reductase, ADH short chain dehydrogenase and ferric reductase domains (Bushley and Turgeon, 2010). Only a few compounds, such as atromentin and microperforanone, have been identified as the product of NRPS-like enzymes (Schneider *et al.*, 2008; Yeh *et al.*, 2012). While most fungi produce siderophores, iron-binding compounds, through an NRPS pathway, it was reported that *Rhizopus delemar* produces the siderophore rhizoferrin using an NRPS-independent siderophore (NIS) synthetase that is characterized by an *lucA/lucC* conserved domain (Carroll *et al.*, 2017). Such synthetases have been characterized in bacteria (Carroll and Moore, 2018), but genome analyses suggest that NISs could actually be produced by many fungi.

Certain SMs are not synthesized by conserved core enzymes and are therefore difficult to identify in fungal genomes. Ribosomally synthesized and post-translationally modified peptides (RiPPs) represent a minor class of SMs in fungi (Vogt and Künzler, 2019). In contrast to the previous pathways, RiPPs are directly encoded by genes in the form of a precursor peptide (Yang and van der Donk, 2013). Remarkably, the precursors of the ustiloxin, phomopsin, asperipin-2a and epichloëcyclin RiPPs consist of a signal peptide followed by repeats of the core peptide in between KR signal sequences that are recognized by the kexin Golgi protease for cleavage (Fig. 3(A)) (Vogt and Künzler, 2019). Finally, SMs like kojic acid and psilocybin are also produced by unconventional biosynthetic pathways that do not include any core enzyme, but only enzymes for the modification of the respective precursors (Terabayashi *et al.*, 2010; Fricke *et al.*, 2017).

The Gene Cluster Organization

The core enzymes described above are involved in the production of the first stable intermediate. However, biosynthetic pathways are usually much more complex and can involve many additional modifications of the produced backbone. For example, the production of aflatoxin involves at least 15 tailoring steps after release of the norsolorinic acid precursor from the PKS (Bhatnagar *et al.*, 2003). These modifications are catalyzed by so-called tailoring enzymes with very diverse catalytic activities such as methylation, mono-oxygenation, decarboxylation, etc. (Walsh and Tang, 2017). The number and type of modifications steps after the release of the initial chemical backbone from the core enzymes expand the diversity of biosynthetic pathways and chemical structures (Fig. 2).

In fungi, the genes that encode core and tailoring enzymes in a given pathway often co-localize in the genome and are co-regulated, criteria that define a gene cluster organization (Fig. 3(B)) (Keller and Hohn, 1997). Additionally, these biosynthetic gene clusters (BGCs) can also comprise genes that encode MFS or ABC transporters for SM export or self-protection (Gardiner *et al.*, 2005; Wiemann *et al.*, 2009; Brown *et al.*, 2015; Dolan *et al.*, 2015), transcription factors for BGC regulation (Lyu *et al.*, 2019) and protein decoys for self-protection (Bushley *et al.*, 2013; Yeh *et al.*, 2016). Certain BGCs contain more than one core gene, leading to the production of hybrid molecules. For example, macrolide lactones are produced by a conserved pair of nrPKS and rPKS (Kim *et al.*, 2005), and meroterpenoids are the products of pathways involving PKSs and TCs (Itoh *et al.*, 2010). The diversity of core genes, tailoring genes and their combinations in BGCs makes it possible to produce a large diversity of bioactive compounds from a very limited set of precursors issued from primary metabolism.

How BGCs are formed in fungal genomes remains a matter of debate. A BGC organization has been suggested to facilitate the co-regulation of genes and interactions between enzymes from a given biosynthetic pathway (Hurst *et al.*, 2004; Santoni *et al.*, 2013; Rokas *et al.*, 2018). Another hypothesis suggests that the partial loss of genes from a given pathway would result in the production of toxic intermediates (McGary *et al.*, 2013). Finally, this organization could be the result of accumulated horizontal gene transfers (HGTs) (Rokas *et al.*, 2018). None of these hypotheses has been experimentally tested and thus requires further investigation.

Tight Regulation of Secondary Metabolite Production

Given that SMs often exhibit biological activities that could be detrimental to the producing organisms and that their production costs energy, SMs should be produced only when required. BGCs are tightly regulated to be expressed under very specific conditions.

The first level of regulation involves pathway-specific transcription factors, which are encoded by genes within the BGC they regulate (Lyu *et al.*, 2019) (Fig. 4). The best characterized example of such a local transcription factor is AflR that regulates the production of aflatoxins (Woloshuk *et al.*, 1994). AflR binds to the promoter of the other genes in the BGC and activate their transcription (Fernandes *et al.*, 1998; Ehrlich *et al.*, 1999).

Fig. 4 Tight regulation of secondary metabolite production in fungi. The expression of biosynthetic gene clusters (BGCs) is controlled by several interconnected levels of regulation. BGCs can contain a gene that encode transcription factors that regulate the expression of the other genes in the BGC by binding to their promoters. Global regulators can also directly regulate the expression of fungal BGCs in response to environmental and developmental signals. Expression of fungal BGCs is also regulated through the modification of chromatin, the complex of DNA and histone proteins. Both DNA methylation and post-translational modifications of histones are epigenetic modifications that affect SM production in fungi. The protein structures are representations obtained with the Illustrate program. Reproduced from Goodsell, D.S., Autin, L., Olson, A.J., 2019. Illustrate: Software for biomolecular illustration. *Structure* 27 (11), 1716–1720. (Cell Press). doi:10.1016/J.STR.2019.08.011.

The second level of regulation involves global regulators that control the expression of a number of BGCs in response to developmental and environmental signals (Fig. 4). CreA, AreA and PacC are transcription factors that control BGC expression in response to the carbon source, nitrogen source, and pH, respectively (Lyu *et al.*, 2019). The Velvet and LaeA protein complex regulates BGC expression in response to light (Bayram *et al.*, 2008; Fischer, 2008), while Hap transcription factors control the response to redox status and iron starvation (Reverberi *et al.*, 2012; Wiemann and Keller, 2014; Hortschansky *et al.*, 2017). SM production is also interconnected with fungal development, often linked to conidiation and formation of survival structures like sclerotia (Calvo and Cary, 2015). This coordination involves specific signaling pathways, which are also activated in response to environmental signals (Lind *et al.*, 2018).

The third level of global regulation corresponds to epigenetic modifications (Fig. 4). The conformation of chromatin, the complex of DNA and histone proteins, determine the accessibility of DNA to regulatory proteins (Armeev *et al.*, 2019). Changes between euchromatin (open state) and heterochromatin (closed state) are especially determined by post-translational modifications of histones, mainly acetylation and methylation (Turner, 2007). As a result, BGCs located in euchromatin can be activated while BGCs located in heterochromatin remain silent (Strauss and Reyes-Dominguez, 2011). This research field has seen much progress in the last decade and a histone code for active and silent BGCs could be determined. BGC expression is mainly linked to acetylation of lysine residues in H3 and H4 histone proteins (Nützmann *et al.*, 2011; Gacek and Strauss, 2012; Soukup *et al.*, 2012; Nützmann *et al.*, 2013). In contrast, tri-methylation of lysine residues in H3 histones are a hallmark of BGC repression (Reyes-Dominguez *et al.*, 2010; Gacek and Strauss, 2012; Connolly *et al.*, 2013; Stoldt *et al.*, 2016). Several histone acetyltransferases and deacetylases, as well as histone methyltransferases and demethylases, have been characterized in fungi and were shown to impact the expression of several BGCs in a given fungus (Collemare and Seidl, 2019). However, BGC regulation by these enzymes is complex because altering the acetylation or methylation status of histones usually results in both activating and repressing different BGCs (Lee *et al.*, 2009; Connolly *et al.*, 2013; Rösler *et al.*, 2016). Although less studied because of its low abundance in fungi, DNA methylation was also found to modify SM production in several fungi, including *Aspergillus* and *Fusarium* species (Williams *et al.*, 2008; Fisch *et al.*, 2009; Yang *et al.*, 2016). More detailed information about each kind of regulation can be found on recent extensive reviews dedicated to this topic (Collemare and Seidl, 2019; Pfannenstiel and Keller, 2019).

Genomics of Fungal Secondary Metabolism

The study of fungal SMs had been focused on their diverse biological activities and functions until the advent of genomes. Since then, the genomics era has provided new research questions, especially regarding the origin and evolution of BGCs, and new tools to investigate fungal SMs. The number and diversity of available fungal genomes is increasing every day thanks to the development of Next

Generation Sequencing (NGS) technologies and the consequential drop in sequencing cost. The public repositories NCBI and Joint Genome Institute MycoCosm portal (Grigoriev *et al.*, 2014) currently host around 2000 and 1400 fungal genomes, respectively. This wealth of genomic information allows for the exploitation of a treasure trove in terms of biochemical reactions and biological activities.

Abundance of Biosynthetic Pathways in Fungal Genomes

The regain of interest in fungal SMs is certainly due to the availability of fungal genomes. For a given fungus, only a few SMs can be detected under standard laboratory conditions. However, genome analyzes have revealed that fungal species possess a much higher SM production capacity with many BGCs in their genomes remaining silent under laboratory conditions. These silent BGCs encode so-called cryptic biosynthetic pathways. For example, the genome of the well-studied model fungus *Aspergillus nidulans* contains 58 predicted BGCs, but we know the corresponding SM for only 26 of them (Romsdahl and Wang, 2019). The explanation for this discrepancy is the tight regulation of SM production under specific environmental conditions that are difficult to identify and reproduce in the laboratory.

Predicted numbers of core genes highlighted the very high SM production capacity of Ascomycota (Fig. 5). Apart from Saccharomycotina and Taphrinomycotina, the average number of core genes in Ascomycota genomes varies between 12 and 68 (Fig. 5). Basidiomycota fungi, which includes edible mushrooms and wood-decaying species, exhibit a more moderate production capacity with a predominance of NRPS-like and TC genes. With the exception of the Neocallimastigomycetes that are especially rich in NRPS genes, the other fungal lineages show a reduced SM production capacity (Fig. 5).

Even though more than 15,000 fungal SMs are reported in the Natural Product Atlas (van Santen *et al.*, 2019) (an open database of SM compounds curated by the scientific community), characterization of the BGCs behind their synthesis is still scarce. The largest collection of characterized BGCs is the Minimum Information about a Biosynthetic Gene cluster (MIBiG) (Medema *et al.*, 2015; Kautsar *et al.*, 2019), which currently contains around 270 fungal BGCs. This limited number of characterized BGCs and the observation that most of fungal BGCs predicted in fungal genomes are silent, highlight the task that is ahead. Especially, the correct identification and prioritization of silent BGCs using bioinformatic approaches are crucial before embarking on lengthy characterization efforts.

Fig. 5 Abundance of biosynthetic pathways in fungal genomes. Number of fungal genomes and predicted core genes in these genomes were retrieved from the Joint Genome Institute MycoCosm repository (November 7, 2019). Reproduced from Grigoriev, I.V., *et al.*, 2014. MycoCosm portal: Gearing up for 1000 fungal genomes. Nucleic Acids Research 42 (D1), D699–D704. doi:10.1093/nar/gkt1183.

Table 1 Software dedicated to the prediction and analysis of biosynthetic gene clusters (BGCs) in fungi

Name	Main Function	Latest publication	Availability	Remarks
SMURF	BGC prediction	(Khaldi <i>et al.</i> , 2010)	Webserver: http://smurf.jcvi.org	Motif-dependent prediction. Flexible BGC borders. Not updated anymore
fungiSMASH	BGC prediction	(Blin <i>et al.</i> , 2019)	Webserver: https://fungismash.secondarymetabolites.org Open source: https://docs.antismash.secondarymetabolites.org/install	Motif-dependent prediction. Fixed BGC borders. Active development
CASSIS	Fungal BGC border detection	(Wolf <i>et al.</i> , 2016)	Webserver: https://sbi.hki-jena.de/cassis/ Open source: https://sbi.hki-jena.de/smips/Download.php fungiSMASH module	Predict co-regulation by searching shared motifs in gene promoters Incorporated in fungiSMASH 4 (but currently not available in fungiSMASH webserver version)
MIDDAS-M	BGC prediction	(Umemura <i>et al.</i> , 2013)	Not available	Motif-independent prediction using gene co-expression
MIPS-CG	BGC prediction	(Takeda <i>et al.</i> , 2014)	Not available	Motif-independent prediction using non-syntenic blocks
FunGeneClusterS	BGC prediction	(Vesth <i>et al.</i> , 2016)	Webserver and open source: https://fungiminions.shinyapps.io/FunGeneClusterS/	BGC identification from gene co-expression
NaPDos	Phylogenetic analysis	(Ziemert <i>et al.</i> , 2012)	Webserver: http://napdos.ucsd.edu	Phylogeny of key biosynthetic domains
MultiGeneBlast	Comparative genomics	(Medema <i>et al.</i> , 2013)	Open source: http://multigeneblast.sourceforge.net	Used as a base for the KnownClusterBlast module in fungiSMASH
BiG-SCAPE	Comparative genomics	(Navarro-Muñoz <i>et al.</i> , 2019)	Open source: https://git.wur.nl/medema-group/BiG-SCAPE	Creates sequence similarity networks and defines BGC families
none	Comparative genomics	(Theobald <i>et al.</i> , 2018)	Open source: https://github.com/RoerdamAndersenLab/gene_cluster_networks_and_genetic_dereplication	Creates sequence similarity networks and defines BGC families

In Silico Prediction of Biosynthetic Gene Clusters

In silico prediction of BGCs usually starts with the detection of the core genes, which requires good quality genome assemblies and, more importantly, accurate gene prediction. While this can be accomplished with simple BLAST searches using reference data, several *in silico* BGC mining tools have been created to facilitate this process (Ziemert *et al.*, 2016), with most of them falling into two categories: motif-dependent and motif-independent detection. It is noteworthy to mention that many tools have been superseded or are not updated anymore, and in some cases, they only exist as a web tool with no open source code (Table 1).

Motif-dependent detection

This approach is based on the conserved sequences (domains) that characterize the SM core enzymes of the most commonly found biosynthetic classes. Protein conserved domains can be encoded as probabilistic mathematical models (hmm: hidden Markov model) that are built from multiple sequence alignments. The frequencies of every amino acid at each position in the alignment are recorded into a so-called profile and then used by software like HMMER (hmm.org) to search and score similar sequences (Eddy, 1998). Nowadays, two tools that make use of hmm profiles (from the Pfam (El-Gebali *et al.*, 2019), TIGRFAM (Haft *et al.*, 2001) or custom-made databases) are predominantly employed to predict BGCs in fungal genomes with high confidence (Medema and Fischbach, 2015).

SMURF was the first tool specifically designed to detect fungal BGCs (Khaldi *et al.*, 2010). This tool uses domain detection not only to find NRPS, PKS, PKS/NRPS hybrid, NRPS-like, PKS-like and DMATS core enzymes in predicted proteomes, but also to find tailoring enzymes. These proteins are also commonly characterized by conserved domains and SMURF relies on a dataset of conserved domains found in 22 BGCs from *Aspergillus fumigatus*. Once a core gene is found, 20 genes upstream and downstream are scanned for the presence of tailoring SM domains and are either tagged as “SM domain positive” or “SM domain negative”. The algorithm keeps scanning genes until (a) the 20-gene window is over; (b) a maximum intergenic distance to the next gene is found; or (c) a maximum number of “SM domain negative” genes are found. While this strategy is flexible to account for the different BGC configurations, its parameters are based on a very limited dataset *A. fumigatus* BGCs. Although SMURF is available online, it is not actively developed anymore.

Just after the release of SMURF, the first version of antiSMASH was published (Medema *et al.*, 2011), which follows the same principle of detecting core genes using profile hmms. antiSMASH was originally developed for mining bacterial BGCs, but it is nevertheless capable of finding all the usual fungal BGC types due to the fact that core enzymes are conserved in both kingdoms.

Then, a region defined by a simple extension of the up- and downstream sequences from the core gene(s) position(s) is reported as containing a BGC. Currently, version 5 of antiSMASH brought a complete revision of the code base, a new conceptual organization for the locus with biosynthetic genes (core, neighborhood, candidate gene cluster and region), and detection of fungal RiPP BGCs that resemble the ustiloxin BGC (Blin *et al.*, 2019). antiSMASH is actively maintained and can be used through the online web version, installed locally or used through Docker. It is worth noting that the fungal version of antiSMASH, named fungiSMASH, does not accept unannotated genomes, meaning that accurate gene prediction in the genome of interest has to be performed beforehand.

While detecting core genes is relatively straightforward, finding the borders of a given BGC is the major challenge in BGC prediction. Both SMURF and antiSMASH show low accuracy in predicting BGC borders. The key difference between fungiSMASH and the regular antiSMASH was the incorporation of the CASSIS algorithm to predict BGC borders (Wolf *et al.*, 2016; Blin *et al.*, 2017). In a given predicted BGC region, CASSIS reports genes that share a motif in their promoter region as this motif would indicate their potential co-regulation. A set of 38 characterized BGCs from *Aspergillus* spp. was used to determine CASSIS parameters.

Both SMURF and antiSMASH suffer from several limitations because they can only detect the major known core enzymes and they cannot report complete BGCs when they are dispersed at more than a single locus (e.g., cephalosporin (Singh *et al.*, 2019), melanin (Langfelder *et al.*, 2003), dothistromin (Schwelm and Bradshaw, 2010)) (Medema and Fischbach, 2015). In addition, the prediction of BGC borders is in most cases inaccurate and manual curation of the results is highly recommended, including validation of functional annotations. Many tools to predict substrate specificities and produced compounds are available either as standalone or integrated into antiSMASH. However, most of them are based on bacterial data and are most often inaccurate when applied to fungal sequences. Functional characterization of many more fungal BGCs is needed in order to develop accurate prediction tools.

Motif-independent detection

Considering the limitations of motif-dependent detection tools, other strategies have been employed to comprehensively identify BGCs in fungal genomes, including non-classical pathways (Umemura *et al.*, 2015). A first strategy is based on the observation that genes from the same biosynthetic pathway are co-regulated, even when they do not contain a classical conserved core gene. Such a strategy was developed in the MIDDAS-M algorithm which averages gene expression over a gene-window and normalizes expression ratios to yield significantly larger values for BGCs (Umemura *et al.*, 2013). This algorithm applied to several fungal species not only accurately reported characterized BGCs, but also identified a new BGC for the RiPP ustiloxin B in *Aspergillus flavus*, which was functionally validated through targeted gene deletion (Umemura *et al.*, 2013). Limitations of this approach are its dependency to experimental data and its ability to detect only the few BGCs that are expressed under laboratory conditions.

Comparative genomic analyzes revealed that fungal BGCs tend to be located in non-syntenic blocks (NSBs) (Machida *et al.*, 2005; Amselem *et al.*, 2011; Collemare *et al.*, 2014; Lind *et al.*, 2017). This observation led to the development of MIPS-CG, which attempted to detect novel BGC candidates by searching for conserved clustered genes between genomes in NSBs (Takeda *et al.*, 2014). This approach is independent of any prior knowledge on fungal BGCs, allowing the successful prediction of non-classical biosynthetic pathways as exemplified with the detection of the kojic acid BGC in *Aspergillus oryzae* (Takeda *et al.*, 2014).

Both MIDDAS-M and MIPS-CG tools are actually not available anymore, but the logic behind these tools can be easily implemented in tailor-made methods to study genomes of interest. The combination of motif-dependent and motif-independent strategies was also tested in *A. nidulans* by linking SMURF predictions to microarray expression data from diverse conditions (Andersen *et al.*, 2013). In this study, the expression data was used to calculate a Cluster Score as a measure for gene co-expression, which accurately predicted that two distant BGCs are responsible for the production of the hybrid peptide-terpene compound nidulanin A. FunGeneClusterS, a graphical online tool with an improved algorithm, was released in a follow up work (Vesth *et al.*, 2016).

Strategies for Prioritizing the Study of Biosynthetic Gene Clusters

Considering the large amount of predicted BGCs in fungal genomes, prioritization of BGCs for functional characterization is needed. Several strategies can be employed to select candidate BGCs that are likely to produce novel compounds or variations of known compounds (Bertrand and Sorensen, 2018; Kjærboelling *et al.*, 2019).

Phylogeny-informed prediction

General phylogenetic studies of core enzymes have been used to elucidate their evolutionary histories (nrPKS (Koczyk *et al.*, 2015)) and to define broad evolutionary clades that relate to enzymatic activities, often by focusing on a single domain (sesterterpenes (Narita *et al.*, 2017), nrPKS (Liu *et al.*, 2015; Throckmorton *et al.*, 2015), NRPS (Bushley and Turgeon, 2010)). Phylogenetic analyzes of core enzymes indicated that closely related core enzymes show functional homology as exemplified with nrPKSs involved in the production of emodin-like anthraquinones (Collemare *et al.*, 2014; Griffiths *et al.*, 2016) or siderophore synthetases (Bushley and Turgeon, 2010). This principle can be used to link BGCs with known metabolites (e.g., (Gibson *et al.*, 2014)) and to directly target novel BGCs whose core enzymes are divergent from characterized ones (Harvey *et al.*, 2018). NaPDos is a bioinformatic tool that was developed to perform functional predictions based on the phylogeny of key domains from characterized PKS (KS domain) and NRPS (C domain) enzymes (Ziemert *et al.*, 2012). While this phylogenetic approach is very useful, predictions of the final chemical structures is not possible because tailoring enzymes modify the backbone produced by the core enzymes. It is therefore crucial to employ also strategies that consider whole BGCs.

Comparative genomics and gene cluster families

Comparative genomics is based on pairwise comparisons between a query and a set of BGCs (“one-to-many”). One of the classical tools for pairwise BGC comparison is MultiGeneBlast (Medema *et al.*, 2013), which has been incorporated into antiSMASH in two analysis modules. A first module (ClusterBlast) compares each query BGC against predicted BGCs from antiSMASH DB (Blin *et al.*, 2018) (currently holding bacterial BGCs only), while the other module (KnownClusterBlast) compares the query against the set of characterized clusters from MIBiG (Medema *et al.*, 2015; Kautsar *et al.*, 2019). These tools remain of limited interest for fungal BGCs until a significant higher number of BGCs will become functionally characterized.

A more integrative approach makes use of sequence similarity networks (SSN) to provide a “many-to-many” overview, automatically defining gene cluster families (GCFs). GCFs corresponds to groups of BGCs that share a common origin and have diverged, resulting in the production of diverse, yet related, SMs. For example, BiG-SCAPE processes antiSMASH results, annotating protein domains in all regions containing a predicted BGC to define a distance matrix based on three components (domain content similarity, synteny and sequence identity) (Navarro-Muñoz *et al.*, 2019). Clustering into GCFs is performed using an affinity propagation algorithm on the resulting distance matrix. BiG-SCAPE accuracy was validated by comparing the GCF calling to metabolomics data for a bacterial case. In principle, BiG-SCAPE could also be used with fungal BGCs.

A similar approach was employed using BGC prediction with a modified version of SMURF in 32 *Aspergillus* spp. (Theobald *et al.*, 2018). The developed method aggregated percentages of identity of best bidirectional hits for each protein in the predicted BGCs, resulting in similarity scores that are translated into a BGC network. A random-walk algorithm is then applied to the network to define GCFs. In combination with expert knowledge of the malformin chemical structure, this method allowed to link malformin to a GCF in *Aspergillus* species, of which one BGC in *Aspergillus brasiliensis* was experimentally confirmed.

Function-guided prioritization

A different approach for BGC prioritization is not based on sequence comparisons but on researcher’s interest in specific enzymatic functions. For example, new chlorinated polyketides from *Bipolaris sorokiniana* were discovered by selecting predicted BGCs which contain genes encoding halogenases (Han *et al.*, 2019).

The same strategy was successfully applied to search for BGCs that would produce SMs with specific biological activities. Several characterized BGCs contain a gene that encodes the enzymatic target of the SM, acting as a decoy and thus providing resistance to the toxic compound (Almabruk *et al.*, 2018). For example, the cyclosporine A BGC contains a gene encoding cyclophilin, the target of cyclosporine (Yang *et al.*, 2018). Such a strategy successfully identified the BGCs involved in the production of mycophenolic acid (MPA) in *Penicillium brevicompactum* (Regueira *et al.*, 2011) and aspterric acid in *Aspergillus terreus* (Yan *et al.*, 2018). The MPA BGC was identified in a cosmid library searching for a meroterpenoid BGC that would contain a copy of IMP dehydrogenase, the known target of MPA in B and T lymphocytes (Regueira *et al.*, 2011). The aspterric acid BGC was identified in the search for herbicides that target the enzyme dihydroxyacid dehydratase (DHAD) involved in the plant-essential branched chain amino acid pathway. Mining of fungal genomes for BGCs that contain a DHAD copy retrieved the aspterric acid BGC, which was functionally validated (Yan *et al.*, 2018).

Resistance gene-directed discovery has been implemented in ARTS (Alanjary *et al.*, 2017), a web tool for discovery of bacterial BGCs with different resistance mechanisms. Very recently, a similar pipeline called FRIGG has been designed for fungi (Kjærboelling *et al.*, 2019). This tool combines precomputed homolog protein families from different genomes with predicted BGCs. In this case, BGCs that contain genes homologous to genes present outside of the cluster may indicate they encode the target of the corresponding SM. Experimental validation of the FRIGG pipeline is still awaiting.

Linking Compounds to Biosynthetic Genes

Screenings for biological activities have resulted in the identification of many compounds from diverse fungi. In most cases, the BGCs behind these compounds is not known. When the genome of a given fungus becomes available, it is possible to implement the strategies mentioned above to select candidate BGCs to study. For this purpose, expert knowledge of the compound chemical structure is necessary to target specific biosynthetic classes using a “retro-biosynthetic” approach. The chemical structure will provide hints about the major chemical classes (polyketide, peptide, etc.) and the needed tailoring reactions (methylation, halogenation, dimerization, etc.). For example, the BGC involved in the production of aspirochlorine was identified thanks to the presence of an halogenase gene that correlate with the chlorinated residue found in this SMs (Chankhamjon *et al.*, 2014). Such a method can also apply to non-classical biosynthetic pathways. The genomes of psilocybin-producers *Psilocybe cubensis* and *Psilocybe cyanescens* were interrogated for the presence of clustered genes that would encode a methyltransferase, a hydroxylase, and a kinase, which are expected for psilocybin biosynthesis. This search retrieved a conserved locus between both species harboring all the expected genes and the predicted BGC was subsequently proven to be responsible for psilocybin production (Fricke *et al.*, 2017).

If the target compound is a chemical analog of a SM with a characterized BGC, it may be inferred that both compounds share the same biosynthetic origin. In this case, the characterized BGC may be used to guide a comparative genomics analysis. This approach have been applied in the *Aspergillus* genus and candidate BGCs could be identified for the production of novo-funigatonin, ent-cycloechinulin and epi-aszonalenin A and C in *A. fumigatus* and ochrindol in *Aspergillus steynii* (Kjærboelling *et al.*, 2018).

Activation of Silent Biosynthetic Pathways

Bioinformatics has revealed a large number of predicted BGCs in fungal genomes and has made it possible to explore effectively the diversity of naturally encoded pathways *in silico*. At the same time, only a very small fraction of these predicted BGCs are associated with characterized SMs and most pathways remain cryptic because they are not expressed under standard laboratory conditions. In the last 15 years, much effort has focused on methods to induce the expression of these silent BGCs and get access to the wealth of SMs they could produce. Several successful strategies have been developed, from the modification of culture conditions to genetic modifications, taking advantage of the accumulated knowledge about BGC regulation.

Modification of Culture Conditions

The tight regulation of fungal BGCs make them produce SMs under very specific conditions during their lifecycle. The laboratory conditions are usually adjusted for optimal growth and thus lack the specific signals for BGC activation. Considering that environmental signals are known to affect SM production (Takahashi *et al.*, 2013), one approach is to grow the fungus of interest under a variety of conditions (light, temperature, oxygenation, etc.) and substrates (different carbon, nitrogen sources, etc.), so that one of the conditions actually contains a signal required for the activation of a BGC. This approach is known as OSMAC (One Strain, Many Compounds) and has been successfully applied to many fungi. For example, cultivating *A. nidulans* under more than 40 different conditions resulted in the discovery of the compounds aspoquinolone (Scherlach and Hertweck, 2006) and aspernidine A and B (Scherlach *et al.*, 2010). Since the initial OSMAC study that discovered 15 SMs produced by *Aspergillus ochraceus* (Bode *et al.*, 2002), this approach has resulted in the discovery of many SMs as recently reviewed in (Romano *et al.*, 2018). Despite its success, the OSMAC approach can be quite tedious because there is no common signal that could always be used to activate the production of several SMs in many fungi. The multiplication of the conditions to test makes this approach difficult to employ on a large number of fungal species at once.

Nowadays, OSMAC approaches also include the use of chemicals to test their effect on SM production. In particular, chromatin remodeling agents are commonly employed because they provide a more consistent and broader effect on BGC activation due to their epigenetic regulation. Growing fungi in the presence of histone deacetylase inhibitors like suberoylanilide hydroxamic acid (SAHA) and of DNA methyltransferase inhibitors like 5-azacytidine resulted in successful activation of SM production in many studies (Henrikson *et al.*, 2009; Wang *et al.*, 2010; Vervoort *et al.*, 2011; Zutz *et al.*, 2013).

Co-Cultivation of Microorganisms

In contrast to competition-deprived laboratory conditions, fungi reside in natural habitats that are normally occupied by many other organisms, including bacterial and fungal competitors. The production of SMs is important to interact or fight with these other organisms. Co-cultivation of organisms (for example, bacteria with fungi or fungi with fungi) is used to mimic competition in natural habitats and induce SM biosynthesis. For example, co-culture of two extremophile *Penicillium* species from the Berkeley Pit Lake yielded eight new macrolide lactones (Stierle *et al.*, 2017). Similarly, co-culture of *A. nidulans* with the soil-dwelling actinomycete *Streptomyces rapamycinicus* demonstrated elevated synthesis of several polyketides, such as orsellinic acid, its derivative lecanoric acid, and two cathepsin K inhibitors, F-9775A and F-9775B (Schroeckh *et al.*, 2009). Co-cultivation of the human pathogen *A. fumigatus* with soil dwelling actinobacteria also induced the synthesis of the meroterpenoid fumicycline (König *et al.*, 2013). Physical contact with living bacteria seems necessary to trigger SM production because in both cases induction was not accomplished by supplementing fungal axenic culture with bacterial media, sterilized bacteria cultivation supernatant or co-cultivation with physical separation of organisms with dialysis tube.

The induction of SM production in co-cultures appears very specific because a single species out of 58 different *Streptomyces* bacteria induced SM production in *A. nidulans* (Schroeckh *et al.*, 2009). Such a specificity makes the outcome of the co-culture approach difficult to predict. The underlying molecular mechanism(s) has not been deeply investigated yet, but the co-culture of *A. nidulans* with *S. rapamycinicus* was showed to trigger modifications of fungal histone acetylation (Nützmann *et al.*, 2011). Higher acetylation at the locus of the transcription factor gene *basR* induced its expression, which in turn activated the expression of BGCs (Fischer *et al.*, 2018). Recently, it was shown that the bacterium *Pseudomonas piscium* suppressed SM production in *Fusarium graminearum* by secreting the histone acetyltransferase inhibitor phenazine-1-carboxamide (Chen *et al.*, 2018). Overall, it appears that the specific effect of co-cultures relies on the active secretion of SMs that trigger a general response in the fungus, either activation or suppression of SM production.

Genetic Modifications

Pathway-specific activation

Biosynthetic pathways can be regulated by BGC-specific transcription factors that are encoded within the corresponding BGC (Fig. 4). A strategy to activate a silent BGC which contains a transcription factor gene is thus to overexpress this regulatory gene. Such an overexpression can be achieved by introducing an extra copy of the transcription factor gene that is under the control of a constitutive or inducible promoter at another locus in the genome. This strategy successfully activated a silent PKS-NRPS BGC in

A. nidulans, leading to the discovery of aspyridone (Bergmann *et al.*, 2007). Instead of adding an extra copy of the transcription factor gene, an alternative strategy is to replace the native promoter of the regulatory gene. For example, replacement by the inducible *alcA* promoter of the promoter of the transcription factor gene found in a silent gene cluster with two PKS genes in *A. nidulans*, successfully induced the targeted BGC and yielded the new polyketide asperfuranone (Chiang *et al.*, 2009). However, in some cases, over-expression of the transcription factor gene does not result in BGC activation as shown for the fellutamide B BGC in *A. nidulans* (Yeh *et al.*, 2016). Activation of this silent BGC and discovery of fellutamide B was accomplished by serial promoter swap for each gene of this BGC.

Genetic manipulation of the global regulation

The study of BGC global regulation, involving both global regulators and epigenetic modifications (Fig. 4), through targeted gene deletion and over-expression resulted in the activation or repression of many BGCs at once. Thus, these functional studies were further developed as a strategy to activate silent BGCs. One of the most studied global regulators is the complex formed by Velvet proteins and LaeA. In *A. nidulans*, deletion of *LaeA* impairs the production of penicillin, sterigmatocystin and lovastatin, while over-expression increases penicillin and lovastatin production (Bok and Keller, 2004). Similarly, manipulation of other Velvet complex components leads to diverse effects on different BGCs. For example, deletion of *FfVel1* in *F. fujikuroi* resulted in the stimulation and down-regulation of bikaverin and fumonisin, respectively, while it did not influence fusarin C production (Wiemann *et al.*, 2010). Application of *LaeA* over-expression in the non-model fungus *Aspergillus fumigatus* successfully activated the production of a new compound in this fungus, which was identified as the known SM cyclopiazonic acid (Hong *et al.*, 2015).

Preferred targets for genetic modifications are genes involved in post-translational modifications of histones. Acetylation of histone proteins is commonly associated with active gene transcription, while their methylation is commonly associated with repression of gene expression (Strauss and Reyes-Dominguez, 2011). Consistently, the deletion of histone deacetylases (HDACs) and histone methyltransferases activates silent BGCs (Shwab *et al.*, 2007; Bok *et al.*, 2009). Similarly, over-expression of histone acetyltransferases activates SM production as shown in *A. nidulans* (Soukup *et al.*, 2012). In contrast, deletion of histone acetyltransferases and histone demethylases mostly results in reducing SM production (Gacek-Matthews *et al.*, 2015; Rösler *et al.*, 2016). Because the deletion of HDACs results in hyperacetylated chromatin and thus active gene transcription (Eberharter and Becker, 2002), these enzymes have been the preferred target to activate silent BGCs and SM production in a number of fungi (Lee *et al.*, 2009; Studt *et al.*, 2013; Maeda *et al.*, 2017; Pidroni *et al.*, 2018). A detailed overview of fungal chromatin-modifying enzymes that can be used as targets for deletion or overexpression has recently been published (Pfannenstiel and Keller, 2019).

Despite the success of this strategy to induce the expression of silent BGCs, their effect is more complex and cannot be predicted. For example, while deletion of the Gcn5 histone acetyltransferase in *F. fujikuroi* decreased the expression of most BGCs, the production of bikaverin was unexpectedly increased (Rösler *et al.*, 2016). In all examples mentioned above, both activation and repression of BGCs were actually found. In other fungi, manipulation of these global regulators only alters the production of already active BGCs and do not activate the production of any new SM (Griffiths *et al.*, 2015).

Heterologous Expression of Biosynthetic Gene Clusters

A major limitation to the genetic modifications mentioned above is that they can be efficiently implemented only in tractable fungal species. Thus, their use remains limited to mostly model fungi and does not allow exploiting the full SM production potential of fungi. An alternative that has been increasingly employed is to express BGCs in heterologous hosts (Skellam, 2019).

The cloning of large PKS and NRPS genes, as well as complete BGCs, is a challenge that was overcome, thanks to cloning technologies like Gateway (Reece-Hoyes and Walhout, 2018) and Golden Gate (Engler and Marillonnet, 2014), as well as the use of transformation-associated recombination (TAR), a method that relies on homologous recombination to assemble several overlapping DNA fragments in *Saccharomyces cerevisiae* (Kouprina and Larionov, 2016) and in *Escherichia coli* (Jacobus and Gross, 2015). Several cloning systems have been developed for heterologous expression of multiple genes in a fungal host, giving the possibility to express complete BGCs (Ishiuchi *et al.*, 2012; Pahirulzaman *et al.*, 2012; Nielsen *et al.*, 2013; Unkles *et al.*, 2014; Bok *et al.*, 2015; Gressler *et al.*, 2015; Geib and Brock, 2017).

Both yeast and filamentous fungi have been used as suitable heterologous hosts. *S. cerevisiae* benefits from decades of biotechnological development for protein and metabolite production. Engineering *S. cerevisiae* for successful SM production is required, especially for the production of polyketides and non-ribosomal peptides, which core enzymes need to be activated by a 4-phosphopantetheinyl transferase (Ishiuchi *et al.*, 2012; Billingsley *et al.*, 2016; Harvey *et al.*, 2018). In addition, incorrect splicing of foreign genes in yeast is commonly encountered, meaning that intron-less genes should be amplified for successful expression (Billingsley *et al.*, 2016; Harvey *et al.*, 2018).

Many different species of filamentous fungi have been used for heterologous expression, mostly from the *Aspergillus* genus (*A. nidulans*, *A. niger*, *A. oryzae*) (Pahirulzaman *et al.*, 2012; Chiang *et al.*, 2013; Richter *et al.*, 2014). *Penicillium* and *Fusarium* species have also been reported as suitable host for heterologous expression of fungal BGCs (Kindinger *et al.*, 2019; Nielsen *et al.*, 2019). So far, the most used host has been *A. oryzae* as it benefits from a long biotechnological development for fermentation processes, which makes this fungus suitable for safe production of enzymes and metabolites. Currently, the *A. oryzae* NSAR1 strain is becoming the main host for the expression of fungal BGCs, because its four auxotrophic markers make it suitable to transform with several plasmids harboring different

selection markers and safe to use as it cannot survive if unintentionally released to the environment (Jin *et al.*, 2004; Skellam, 2019). Intron splicing in filamentous fungal hosts is less of an issue than in yeast, but the foreign genes are not always accurately processed as exemplified by the attempts to express the *ACE1* gene from *P. oryzae* in *A. oryzae* (Song *et al.*, 2015).

Heterologous expression has mainly been applied to single targeted BGCs. A scaled-up heterologous expression system was designed, making use of fungal artificial chromosomes and metabolomic scoring (FAC-MS) (Clevenger *et al.*, 2017). A library of 156 FACs from *Aspergillus wentii*, *Aspergillus aculeatus* and *A. nidulans* was transformed into *A. nidulans*. Analysis of SMs produced by the transformants yielded 15 new SMs and their corresponding BGCs. Although successful, this method requires conserved signaling pathways and thus can only be applied in closely related fungal species.

Nowadays, we are entering a new era in which DNA synthesis is allowing large-scale targeted heterologous expression of silent BGCs. In a recent study, 41 fungal BGCs selected to cover a wide phylogenetic diversity were synthesized and expressed in yeast (Harvey *et al.*, 2018). The production of a SM was detected for 22 of these BGCs, of which 10 were new compounds (Harvey *et al.*, 2018). Incorrect gene structure prediction was suggested to be a major reason for failed SM production in this study. Indeed, manual inspection of intron prediction in the terpene cyclase TC5 identified a wrongly predicted intron and the corrected gene structure expressed in yeast successfully yielded new sesquiterpenoids (Harvey *et al.*, 2018). It is likely that DNA synthesis combined with heterologous expression will become the strategy of choice thanks to the development of new technologies that will lower its cost. The generation of high-quality genomic data and accurate gene prediction will be crucial for the success of large-scale heterologous expression.

Engineering Biosynthetic Pathways: Chimeric Enzymes, Pathway Refactoring, Combinatorial Biosynthesis, Artificial Pathways

The development of heterologous expression methods has been instrumental in elucidating biosynthetic pathways and activating silent BGCs. However, these methods are also opening new biotechnological opportunities towards the production of non-natural SMs.

Studies to understand the biosynthetic mechanisms of core enzymes, especially PKSs and NRPSs, made use of chimeric enzymes that combined conserved domains from different enzymes. For example, a chimeric PKS made of the SAT-KS-AT-PT domains from *Colletotrichum lagenarium* Pks1 and of the ACP-CLC domains from *A. nidulans* wA yielded the production of a novel hexaketide different from the precursor produced by Pks1 and wA (Watanabe and Ebizuka, 2002). Rational domain swapping between core enzymes often result in the production of new SMs which provide information about how these enzymes function, especially about chain length control in PKSs (Fisch *et al.*, 2011; Liu *et al.*, 2014).

Nearly a decade ago, the concept of plug-and-play synthetic biology was suggested as a method to engineer or optimize biosynthetic pathways (Medema *et al.*, 2011). In this concept, all core and tailoring genes are considered as pieces that can be rearranged and optimized in order to increase the production of a given SM or produce new SMs. Such a strategy was recently applied to the austinoid pathway. Austinol is a meroterpenoid compound with insecticide activity produced by *A. nidulans* under favorable fermentation conditions (Mattern *et al.*, 2017). *Aspergillus calidoustus* produces another derivative with higher insecticide activity, calidodehydroaustin, but only under conditions that are not favorable for industrial fermentation (Mattern *et al.*, 2017; Valiante *et al.*, 2017). The comparison of the austinoid BGCs in *A. nidulans*, *A. calidoustus* and *Penicillium brasilianum* identified four candidate genes for the conversion of austinol into calidodehydroaustin (Mattern *et al.*, 2017). Expression of the candidate *A. calidoustus* genes in *A. nidulans* under control of an inducible promoter resulted in successfully rewiring the austinol biosynthetic pathway in *A. nidulans* to produce calidodehydroaustin (Mattern *et al.*, 2017).

The plug-and-play concept allows envisaging combinatorial to produce new compounds. This possibility was exemplified with the study of BGCs involved in the production of macrolide lactones and which encode both an nrPKS and an rPKS. Different combinations of nrPKS and rPKS pairs from related BGCs in different fungal species resulted in the biosynthesis of diverse SMs, including unnatural lactone variants with altered biological activity (Xu *et al.*, 2014).

Theoretically, it is conceivable to create completely artificial pathways using genes from unrelated BGCs. While such an example with fungal sequences has not yet been published, an artificial biosynthetic pathway to produce carminic acid, a red food colorant of insect origin, in *A. nidulans* was recently reported. In this case, a type III PKS gene of plant origin was expressed in *A. nidulans* together with cyclase and aromatase genes of bacterial origin, resulting in the production of the expected carminic acid backbone (Frandsen *et al.*, 2018). This backbone was modified by endogenous monooxygenases, yielding the needed next precursor. The final step of carminic biosynthesis was completed with the expression of a C-glucosyltransferase from the insect *Dactylopius coccus*.

Fungal Secondary Metabolite Production: Future Perspectives

Our fundamental knowledge of fungal SM production has impressively improved in the first two decades of the 21st century, notably thanks to the development of genomics and biotechnological tools. Despite this progress, the study and exploitation of fungal SMs remains behind compared to bacterial SMs as clearly shown by the restricted number of characterized fungal BGCs. Further development of biotechnological tools to fully exploit the SM production capacity of fungi is still hampered from lack of fundamental knowledge.

Active development of bioinformatics tools dedicated to fungal genomes is needed to address several key challenges such as accurate BGC definition, integration of expression data, detection of BGCs split over different loci and evolution of biosynthetic

pathways in GCFs. With the increasing availability of both fungal genomes and characterized data, including transcriptomics and metabolomics data, there is now a timely opportunity to develop new fungal-specific approaches.

Although a better understanding of BGC regulation could provide new tools to activate silent BGCs in the future, biotechnological strategies relying on heterologous expression appear to be the most promising for the efficient production of new fungal SMs. Such strategies will allow obtaining bioactive compounds in industrial-scale quantities, developing semi-synthetic approaches to produce chemical structures that are otherwise difficult to obtain with synthetic chemistry (Asai *et al.*, 2015; Alberti *et al.*, 2017), and building artificial BGCs. These developments require the functional characterization of many more fungal core and tailoring enzymes, especially regarding substrate specificities and interactions between tailoring enzymes. The combination of functional characterizations, bioinformatics and biotechnological tools is promising to lead to the efficient and less labor-intensive production of diverse bioactive SMs of fungal origin.

Introduction

Aromatic compounds are best known for having a distinctive smell (aroma) and are therefore used in many food and beverages for the aroma and flavor. The most known aromatic compounds are the aromatic amino acids phenylalanine, tryptophan and tyrosine. Well known aromatic compounds found in nature are the aromatic compounds vanillin and benzaldehyde, which are responsible for the distinct smell of vanilla and almonds, respectively. Aromatic compounds are chemical compounds which consist of a planar (flat) cyclic structure with alternating single and double bonds. This structure is known as an aromatic ring or benzene ring and the molecule is called benzene (C_6H_6) which was first isolated by Michael Faraday in 1825 and is the least complex aromatic compound (Fig. 1). In order to be an aromatic compound, it must follow the four criteria of the Hückel's rule of aromaticity which states that:

- (1) The molecule must be planar (flat),
- (2) The molecule must be cyclic,
- (3) The ring is completely conjugated,
- (4) It must contain an odd number of pairs of π electrons ($4n + 2$ π -electrons, in which n = non-negative integer).

Homocyclic aromatic compounds contain only carbon atoms in the ring, while heterocyclic aromatic compounds contain non-carbon atoms such as oxygen, nitrogen or sulfur in their ring (Fig. 1). For example, pyridine and purine are both heterocyclic aromatic compounds. In addition, aromatic compounds can also consist of multiple benzene rings and are called polycyclic aromatic compounds. For example, naphthalene ($C_{10}H_8$) consists of two fused benzene rings and can be extracted from coal tar. This compound is used as the main ingredient of traditional mothballs.

Names of Aromatic Compounds

Aromatic compounds can have multiple atoms attached to its benzene ring and remain aromatic compounds as long as they follow the rules of aromaticity. Many aromatic compounds have several non-systematic names which are discouraged to be used by IUPAC. However, several non-systematic names have been generally accepted. For example, hydroxybenzene is commonly known as phenol, benzene carboxylic acid as benzoic acid, ethylbenzene as styrene and methylbenzene as toluene.

Some substituted benzenes are named using the *ortho* (*o*), *meta* (*m*) and *para* (*p*) nomenclature, e.g., *p*-hydroxybenzoic acid (Fig. 2). However, more preferred is the numbering of the substitutions on the ring by choosing the point of attachment as position 1, while the second substituent has the lowest number as possible. Substituents in the name are written alphabetically, for example 4-hydroxy-3-methoxybenzoic acid. The carbons on the aliphatic chains are labeled with Greek letters starting with alpha (α), beta (β), gamma (γ), etc. (Fig. 2).

Due to the frequent use of non-systematic names, some are preferred over the IUPAC names since they are shorter and more reader friendly. For example, 4-hydroxy-3-methoxybenzaldehyde is the preferred IUPAC name, but this compound is better known through its non-systematic name vanillin.

Plant Derived Aromatic Compounds

In nature, many aromatic compounds exist and most organisms can synthesize aromatic compounds. However, plants and microorganisms are best known for their aromatic compound producing abilities. Many non-benzenoids and heterocyclic aromatic compounds exist, but these are not further discussed in this chapter. Therefore, only homocyclic aromatic compounds are discussed and were selected based on their occurrence in plants, global importance, such as pollution, or their applications in man made products.

Lignin

Plants are able to synthesize the largest polymeric aromatic molecule on Earth, called lignin. Lignin is synthesized from the aromatic amino acid phenylalanine and is converted to cinnamic acid which is one of the key building blocks for the lignin synthesis since it can be converted into the three essential monolignols (Humphreys and Chapple, 2002). Lignin mainly

Fig. 1 Examples of homocyclic, heterocyclic and polycyclic aromatic compounds.

consists of the aromatic monolignols coniferyl alcohol, *p*-coumaryl alcohol and sinapyl alcohol that form the guaiacyl (G), *p*-hydroxyphenyl (H) and syringyl (S) units in lignin, respectively (Freudenberg, 1965; Humphreys and Chapple, 2002) (Fig. 2). Lignin provides for example stiffness and strength of the stem, and structural integrity of the cell wall (Davin and Lewis, 2005; Bhuiyan *et al.*, 2009; Ralph, 2010). These properties are derived by the crosslinking of lignin with other cell wall components and covalent binding to hemicellulose (Ralph, 2010; Mäkelä *et al.*, 2015; Dilokpimol *et al.*, 2017). Therefore, the development of lignin biosynthesis is considered as a crucial step in the colonization of plants from aquatic environments to land (Boerjan *et al.*, 2003; Weng and Chapple, 2010). The hydrophobic property of lignin is also essential for the plant to transport water and solutes through its vascular system. Next to that, lignin also plays a role as a barrier against pests and pathogens, and its metabolism is also involved in the response to abiotic stresses such as temperature, drought and salt stress (Bhuiyan *et al.*, 2009; Liu *et al.*, 2018). The synthesis of lignin in plants is a process that crosslinks monolignols through dimerization and lignification (Faulon and Hatcher, 1994; Boerjan *et al.*, 2003; Davin and Lewis, 2005). Interestingly, the amount and composition of lignin is highly variable among plant species, cell types and cell wall layers, and is even influenced by developmental and environmental cues (Boerjan *et al.*, 2003; Liu *et al.*, 2018). Angiosperm (hardwood) lignin consists mainly of S units, with low amounts of G units and traces of H units, while gymnosperm (softwood) lignin consists mainly of G units with a low amount of S and H

Fig. 2 Nomenclature of the aromatic ring and aliphatic chain.

units. Lignin from grasses (monocots) consists mainly of G and S units, but have a higher ratio of H units compared to angiosperms.

Plant Derived Monomeric Aromatic Compounds

In plants, aromatic compounds can serve as phytohormones, pesticides, anti-microbial agent, anti-nematocidal, repellents or as luring agents to attract insects, etc. Salicylic acid is known to be a phytohormone involved in plant defense signaling and plant development (Vernooij *et al.*, 1994; Shah, 2003; Zhang *et al.*, 2013; Lu *et al.*, 2016). Vanillin and cinnamaldehyde have strong anti-microbial activities and are found in *Vanilla planifolia* and *Cinnamomum verum* plants, respectively. Next to that, aromatic compounds can be part of cell wall components. For example, ferulic acid and *p*-coumaric acid are present in polysaccharides, such as xylan and pectin, and can form cross linkages between them and between polysaccharides and lignin through dimerization (Ralph, 2010; Mäkelä *et al.*, 2015; Dilokpimol *et al.*, 2017). Many aromatic compounds, such as caffeic acid, catechol, cinnamaldehyde, protocatechuic acid (3,4-dihydroxybenzoic acid), salicylic acid, syringic acid and vanillin, are found freely in plants (Link *et al.*, 1929; Link, 1933; Newby *et al.*, 1980; Cherney *et al.*, 1989).

Allelopathy

Aromatic compounds can also be found in high concentrations in soil when they are released during plant decay. Phenolic compounds that are released from plants (and other organisms) are known as allelochemicals, which results in the phenomenon called allelopathy. Allelopathy is the direct or indirect effect of a plant on other organisms, including other plants, through the release of biochemicals in the environment. These biochemicals can have beneficial or disadvantageous effect on the target or the community. For example, protocatechuic acid and catechol that diffuse from dead cell layers from the scales of pigmented onion, inhibit the spore germination and hyphal penetration of the onion fungal pathogen *Colletotrichum circinans* (Link *et al.*, 1929; Link, 1933). Other aromatic compounds, such as benzoic acid, caffeic acid, chlorogenic acid, cinnamic acid, 3,5-dinitrobenzoic acid, ferulic acid, gallic acid, gentisic acid, *p*-coumaric acid, *p*-hydroxybenzaldehyde, *p*-hydroxybenzoic acid, protocatechuic aldehyde (3,4-dihydroxybenzaldehyde), protocatechuic acid, vanillin and vanillic acid, are all suggested as allelochemicals (Chou and Lin, 1976; Whitehead *et al.*, 1982; Chou and Leu, 1992; Politycka, 1997; Sasikumar *et al.*, 2001, 2002).

Lignin Degradation

Fungi are considered to be the most efficient lignin degraders on Earth. Lignin degradation and modification by basidiomycete white-rot and brown-rot fungi has been studied for decades. However, ascomycete fungi are not known to degrade high molecular weight native lignin molecules (Mäkelä *et al.*, 2015, 2020), however exceptions have been observed (van Erven *et al.*, 2020). White-rot fungi have the ability to degrade and modify lignin, hemicellulose and cellulose. This often results in a white cellulose-enriched material, hence the name white-rot fungi. Brown-rot fungi can modify lignin to gain access to the plant cell wall polysaccharides. These lignin modifications result in a brown material of oxidized lignin, hence the name brown-rot fungi. In order to degrade or modify lignin, wood-decaying white-rot basidiomycetes release extracellular oxidative enzymes such as laccases and class II fungal heme peroxidases.

Less is known about the role of bacteria in lignin degradation, even though bacteria that are able to convert or degrade small lignin-derived aromatic compounds have been described previously (Bugg *et al.*, 2011b; Brown and Chang, 2014). Currently, much research is performed in the degradation of small lignin-derived aromatic compounds, especially with the bacterium *Sphingomonas paucimobilis* (Kamimura *et al.*, 2017).

Table 1 Examples of aromatic compounds released by the bacteria *Aneurinibacillus aneurinilyticus*, *Bacillus* sp., *Rhodococcus jostii* and *Sphingomonas paucimobilis* and the fungi *Ceriporiopsis subvermispora*, *Pleurotus eryngii*, *P. chrysosporium* and *Lentinula edodes* during growth on lignin containing substrates

Aromatic compound	Systematic name	Lignin source	Species
3,4,5-Trimethoxy benzaldehyde	—	Kraft lignin	<i>Bacillus</i> sp.
4-Methylguaiacol	—	Wheat straw	<i>C. subvermispora</i> , <i>P. eryngii</i> , <i>L. edodes</i>
Cinnamic acid	(2E)-3-Phenylprop-2-enoic acid	Kraft lignin	<i>Bacillus</i> sp.
Ferulic acid	4-Hydroxy-3-methoxycinnamic acid	Kraft lignin, lignocellulose	<i>A. aneurinilyticus</i> , <i>Bacillus</i> sp. <i>R. jostii</i>
Gallic acid	3,4,5-Trihydroxybenzoic acid	Kraft lignin	<i>A. aneurinilyticus</i>
Guaiacol	2-Methoxyphenol	Wheat straw	<i>C. subvermispora</i> , <i>P. eryngii</i> , <i>L. edodes</i>
<i>p</i> -Coumaric acid	4-Hydroxycinnamic acid	Kraft lignin	<i>Bacillus</i> sp.
Phenol	Hydroxybenzene	Wheat straw	<i>C. subvermispora</i> , <i>P. eryngii</i> , <i>L. edodes</i>
Phenylacetic acid	—	Kraft lignin	<i>A. aneurinilyticus</i>
<i>p</i> -Hydroxybenzoic acid	4-Hydroxybenzoic acid	Kraft lignin, spruce	<i>A. aneurinilyticus</i> , <i>P. chrysosporium</i>
Syringic aldehyde	4-Hydroxy-3,5-dimethoxybenzaldehyde	Lignocellulose	<i>S. paucimobilis</i>
Syringol	1,3-Dimethoxy-2-hydroxybenzene	Wheat straw	<i>C. subvermispora</i> , <i>P. eryngii</i> , <i>L. edodes</i>
Vanillic acid	4-Hydroxy-3-methoxybenzoic acid	Kraft lignin, spruce	<i>A. aneurinilyticus</i> , <i>P. chrysosporium</i>
Vanillin	4-Hydroxy-3-methoxybenzaldehyde	Wheat straw	<i>C. subvermispora</i>

Biotechnology for Biofuels 11, 1–16.

Microbial degradation of lignin results in the release of aromatic compounds, which are toxic already at low concentrations for most microorganisms (Guiraud et al., 1995; Friedman et al., 2003; Adeboye et al., 2014; Lima et al., 2017). In order to survive this toxicity, the aromatic compounds need to be degraded or converted to non- or less toxic compounds by the microorganism. This is usually followed by the cleavage of the aromatic ring to eliminate toxicity, resulting in compounds that can be used as a carbon source. Many aromatic compounds have been observed to be released during bacterial and fungal lignin degradation (Table 1).

Degradation of Aromatic Compounds by Fungi

Most fungi are exposed to aromatic compounds in their environments and are able to degrade them. A common misconception is that aromatic compounds do not serve as carbon source for fungi and that they are only part of secondary metabolic pathways. However, several studies have shown that aromatic compounds can serve as carbon source (Guiraud et al., 1992; Weber et al., 1995; Martins et al., 2015; Lubbers et al., 2019b,a, 2020). The understanding of the microbial aromatic metabolic pathways can reveal, for example, how pathogens evade or suppress the plant defense system and cause diseases, or how some fungi can grow in hazardous environments while others cannot. More importantly, discovery of novel aromatic compound modifying enzymes are of great interest for the valorization of lignin and compounds derived from it. This will offer great opportunities for innovations to produce valuable compounds for many industries, e.g., food, plastic, cosmetic and pharmaceutical industries. To efficiently produce aromatic compounds, microorganisms have been genetically modified to produce desired compounds from glucose through the shikimate pathway or through lignin valorization (Wu et al., 2017; Barton et al., 2018). At this moment, only a few genes involved in the aromatic metabolism of fungi have been identified. Due to the many aromatic compounds present in nature, a selection of common and industrially relevant aromatic compounds will be discussed here.

Hazardous Aromatic Compounds

In this chapter aromatic compounds with hazardous properties are discussed. These aromatic compounds are released during industrial processes. The aromatic compounds benzene, toluene, ethyl benzene and xylenes, also collectively known as BTEX, are used in industrial synthesis and are components of gasoline and aviation fuels. However, BTEX are also contaminants commonly found in soil, sediments, water and the atmosphere, and are released in nature by improper waste disposal, leakages in underground storage tanks and pipelines, and accidental spillages (Nikolova and Nenov, 2005; García-Peña et al., 2008).

Benzene

Benzene is a valuable chemical that is used as precursor for the synthesis of polymers, lubricants, rubbers, resins and synthetic fibers (Gentry, 2007; Nithyanandam et al., 2018). Benzene is mainly converted to cumene, cyclohexane, nitrobenzene and ethylbenzene. More than half of the globally produced benzene is converted to ethylbenzene, of which 99% is converted to

Fig. 3 BTEX metabolic pathways observed in fungi.

Fig. 4 Phenol metabolic pathway in fungi.

styrene. Styrene is used to produce synthetic rubbers and polymers such as polystyrene. Due to the many applications of benzene, the use of benzene is rapidly increasing and a global shortage is expected (Nithyanandam *et al.*, 2018). On the negative side, benzene is carcinogenic and its health risks have been studied for decades (Galbraith *et al.*, 2010; Gross and Paustenbach, 2018). Frequent exposure to high concentrations of benzene can cause non-Hodgkin lymphoma and leukemia, but also aplastic anemia, bone marrow abnormalities and cardiovascular disease (Vigliani and Saita, 1964; Velasco Lezama *et al.*, 2001; Galbraith *et al.*, 2010; Gross and Paustenbach, 2018). Exposure to low concentrations of benzene are primarily from petrol stations, gasoline combustion and tobacco smoke. Since benzene is highly volatile and can easily be inhaled, the exposure to benzene at workplaces is tightly regulated. In addition, the concentrations of benzene in various consumer products has been limited to less than 0.1% (Williams *et al.*, 2008).

Not much is known about the degradation of benzene by fungi. However, degradation of benzene has been observed in the fungi, such as the basidiomycete white-rot fungi *Phanerochaete chrysosporium* and *Trametes versicolor* (Yadav and Reddy, 1993; Aranda *et al.*, 2010). Currently, only one pathway has been described in *T. versicolor*. This fungus converts benzene through hydroxylation, which results in the formation of phenol that is further hydroxylated to catechol (1,2-dihydroxybenzene) (Aranda *et al.*, 2010) (Fig. 3). The metabolism of phenol and catechol is further discussed in Section “Phenol”.

Ethylbenzene

Ethylbenzene naturally occurs in coal tar and petroleum. As mentioned before, ethylbenzene is mainly chemically synthesized from benzene through ethylation. Ethylbenzene is converted to styrene through catalytic dehydrogenation and is used for the production of polystyrene. Interestingly, the dimorphic yeast *Exophiala lecanii-corni* is also able to convert ethylbenzene to styrene (Fig. 3) (Gunsch *et al.*, 2005). It was suggested that styrene is converted to phenylacetate followed by two hydroxylation steps at the 2 and 5 position to homogentisate. Homogentisate is then cleaved to 4-maleylacetoacetate by homogentisate 1,2-dioxygenase. Similar styrene degradation pathways have been observed for the dimorphic yeast *Exophiala jeanselmei* and the white-rot fungus *Pleurotus ostreatus* (Cox *et al.*, 1996; Braun-Lüllemann *et al.*, 1997).

Toluene

The aromatic compound toluene (methylbenzene) can be extracted from crude oil, coal tar and petroleum. It is commonly used as a solvent in adhesives, coatings, paint and thinners but can also be used in fuels as an octane booster. Toluene is a hazardous aromatic compound, which has neurotoxic effects and can cause kidney and liver damage (Win-Shwe and Fujimaki, 2010).

The ascomycete fungus *Cladosporium sphaerospermum* was the first fungus shown to degrade toluene as sole carbon source (Weber *et al.*, 1995). This fungus was isolated from a compost biofilter used for the removal of toluene from waste gases. Degradation of toluene was also observed for two *Cladophialophora* strains and an *Exophiala* strain (Prenafeta-Boldú *et al.*, 2001). Currently, two toluene pathways have been described for fungi. In the first pathway, toluene is converted to benzyl alcohol by a toluene monooxygenase (Weber *et al.*, 1995; Luykx *et al.*, 2003) (Fig. 3). Benzyl alcohol is converted to benzaldehyde catalyzed by benzyl alcohol dehydrogenase. Benzaldehyde is further converted to benzoic acid by a benzaldehyde dehydrogenase. The metabolism of benzoic acid is further discussed below.

The second pathway was observed in the ascomycete fungi *Aspergillus ochraceus* and *Penicillium chrysogenum* (Smith and Rosazza, 1974). Toluene is hydroxylated at the *ortho* position resulting in the formation of *o*-cresol. This pathway was suggested to continue with an additional hydroxylation at *meta* position resulting in the formation of methylcatechol.

Fig. 5 Salicylic acid metabolic pathways in fungi.

Xylenes

Xylene (dimethylbenzene) has three isomers, *o*-xylene, *m*-xylene and *p*-xylene, which are widely used in the printing, rubber and leather industries, and in medical technology. In addition, *p*-xylene is a precursor for terephthalic acid and dimethyl terephthalate, which are used to produce the plastic polyethylene terephthalate (PET). However, xylene is toxic and has effects on the central nervous system, liver, kidney, reproductive system and respiratory track (Langman, 1994; Niaz *et al.*, 2015).

Currently, no metabolic pathways of xylene have been described in fungi. However, *Penicillium* sp. CHY-2, *P. chrysosporium* and *C. sphaerospermum* are able to degrade xylene (Jorio *et al.*, 2009; Chang *et al.*, 2016).

Phenol

The aromatic compound phenol (hydroxybenzene) is used in multiple applications and is mainly used as precursor for plastics and pharmaceuticals such as aspirin, but also for pesticides and herbicides. Phenol in combination with chloroform is also used in the molecular biology for the extraction of DNA and RNA. Phenol is a highly toxic, corrosive and mutagenic aromatic compound and is hazardous for humans, animals and plants at low concentrations (Bruce *et al.*, 1987). High concentrations of phenol can cause central nervous system disorders, myocardial depression and blindness, and harmful effects on the heart, liver and kidneys. Due to the toxicity and solubility in water, phenol is considered a highly hazardous pollutant. Phenol is also a byproduct of many industrial applications and can be found in high concentrations in the wastewater from coal refineries, tanneries, phenol manufacturing pharmaceuticals and industries of dyes, paints, resins, petrochemicals, textiles, pulp, paper and wood products (Senthilvelan *et al.*, 2014; Villegas *et al.*, 2016). In order to remove phenol from industrial wastewater, several methods are used, including adsorption, distillation, extraction, oxidation and membrane separation, but are costly and can yield hazardous byproducts (Mohammadi *et al.*, 2015). However, phenol can still be found in the environment, such as ground water and soil, due to disposal of untreated wastewater or leakages (Kahru *et al.*, 1994; Mohite *et al.*, 2011).

An alternative eco-friendly treatment of phenol containing wastewater is through bioremediation, in which microorganisms degrade phenol as a carbon source or convert it to a non-toxic compound. The biodegradation of phenol by bacteria is studied for decades, but is less studied in fungi. In fungi, two metabolic pathways have been observed (Fig. 4). The *ortho* hydroxylation of phenol results in the formation of catechol and is observed in the ascomycete fungi *Aspergillus fumigatus* (Jones *et al.*, 1993), *Aspergillus niger* (Supriya and Neehar, 2014), *Graphium* sp. FIB4 (Santos *et al.*, 2003; Santos and Linardi, 2004), *Fusarium oxysporum* (Park *et al.*, 2009), *Fusarium* sp. HJ01 (Cai *et al.*, 2007), *Paecilomyces variotii* (Wang *et al.*, 2010) and *Penicillium frequentans* (Hofrichter *et al.*, 1992), and the yeasts *Candida albicans* (Gérecová *et al.*, 2015), *Candida tropicalis* (Ahuatzi-Chacón *et al.*, 2004).

Fig. 6 Metabolism of vanillin and vanillic acid in fungi.

and *Trichosporon cutaneum* (Gaal and Neujahr, 1979). The aromatic ring of catechol is cleaved by an intradiol catechol 1,2-dioxygenase resulting in the formation of *cis,cis*-muconic acid. *Cis,cis*-muconic acid is further converted through the oxoadipate pathway to 3-oxoadipate and is then converted towards the tricarboxylic acid (TCA) cycle.

A second pathway in which phenol is hydroxylated at the *para* position, resulting in the formation of hydroquinone (1,4-dihydroxybenzene), was observed in *A. fumigatus* (Jones *et al.*, 1994), *P. chrysogenum* (Leitão *et al.*, 2007) and the yeast *C. tropicalis* (Gérecová *et al.*, 2015). Hydroquinone is further converted to hydroxyquinol (1,2,4-trihydroxybenzene) by a hydroxyquinol 1,2-dioxygenase to methylacetate and further to 3-oxoadipate.

Plant Derived and Food Related Aromatic Compounds

Salicylic acid

Salicylic acid (2-hydroxybenzoic acid) has many interesting properties and is mainly used as a peeling agent in skin care products (Arif, 2015). In addition, salicylic acid is also a precursor for aspirin and 4-aminosalicylic acid that is used to treat tuberculosis. Salicylic acid is mainly chemically synthesized from phenol through the Kolbe-Schmitt reaction (Kirimura *et al.*, 2010). In plants, the amino acid phenylalanine is converted to salicylic acid. As mentioned before, salicylic acid plays an important role as phytohormone involved in plant defense signaling, plant development, photosynthesis, transpiration and ion uptake and transportation (Vernooij *et al.*, 1994; Shah, 2003; Zhang *et al.*, 2013; Lu *et al.*, 2016). Salicylic acid degradation by fungi is considered to be an important factor for pathogenicity (Rabe *et al.*, 2013; Ambrose *et al.*, 2015; Hao *et al.*, 2019). Multiple salicylic acid degradation pathways have been described (Fig. 5).

The carboxyl group from salicylic acid is decarboxylative hydroxylated by a salicylate hydroxylase to a hydroxyl group resulting in the formation of catechol. This has been observed in the filamentous fungi *A. niger* (Lubbers *et al.*, 2021), *Aspergillus nidulans* (Martins *et al.*, 2015), *Aspergillus japonicus* (Milstein *et al.*, 1983), *Epichloë festucae* (Ambrose *et al.*, 2015), *Fusarium graminearum* (Hao *et al.*, 2019), *Sclerotinia sclerotiorum* (Penn and Daniel, 2013) and *Ustilago maydis* (Rabe *et al.*, 2013), and the yeast *Trichosporon cutaneum* (Sze and Dagley, 1984). As described before, the aromatic ring of catechol is cleaved resulting in the formation of *cis,cis*-muconic acid. In the second pathway, salicylic acid is first hydroxylated at the *meta* position resulting in the formation of 2,3-dihydroxybenzoic acid (Martins *et al.*, 2015). Thereafter, 2,3-dihydroxybenzoic acid is decarboxylated to catechol which is catalyzed by 2,3-dihydroxybenzoate decarboxylase (DhbA) (Santha *et al.*, 1995; Martins *et al.*, 2015). A third pathway was observed in *Neurospora crassa*, which is able to reduce salicylic acid to salicylaldehyde (2-hydroxybenzaldehyde) and saligenin (2-(hydroxymethyl)phenol) (Bachman *et al.*, 1960).

Vanillin

One of the best-known aromatic compounds is vanillin (4-hydroxy-3-methoxybenzoic acid) that is used for its sweet and appealing aroma. In addition, vanillin has antimicrobial activities and can be used as preservative (Fitzgerald *et al.*, 2003, 2004;

Ngarmsak *et al.*, 2006). Vanillin can be found naturally in the seed pods of vanilla orchids (*Vanilla planifolia*). Currently, vanillin is one of the most important flavor and fragrance compounds in food and cosmetics. Next to that, vanillin is also used as precursor in pharmaceuticals such as dopamine and papaverine. A promising industrial niche is the increasing consumer demand for “naturally” produced aromatic compounds. Only 0.2% of vanillin is derived from natural sources, while the rest is produced from guaiacol by chemical synthesis (Krings and Berger, 1998). Therefore, the production of vanillin by microorganisms is of great interest. Vanillin is also a flavoring agent of the traditional Japanese spirit, awamori. Ferulic acid (4-hydroxy-3-methoxycinnamic acid) that is present in rice koji (cooked rice) is converted to vanillin during the fermentation with *Aspergillus luchuensis*. The aromatic compounds ferulic acid, vanillin and vanillic acid were detected in rice koji and during fermentation (Maeda *et al.*, 2018; Taira *et al.*, 2018). Two metabolic pathways have been described, which result in the formation of vanillin. In the CoA-independent oxidative pathway, ferulic acid is decarboxylated to vinyl-guaiacol by the phenolic acid decarboxylase (Pad) and is further reduced to vanillin (Taira *et al.*, 2018). In the CoA-dependent non-oxidative pathway, ferulic acid is converted to feruloyl-SCoA by an feruloyl-CoA synthetase (Fcs). The next two steps are catalyzed by a multifunctional enzyme called enoyl-CoA hydratase/aldolase (Ech) which hydrates feruloyl-SCoA to HMPHP-SCoA and cleaves it to vanillin and acetyl-CoA. Currently, it remains unknown which metabolic pathway is used by *A. luchuensis*.

Fungi can degrade vanillin through multiple aromatic metabolic pathways (Lubbers *et al.*, 2019c). The foremost observed pathway is the dehydrogenation of vanillin to vanillic acid or reduction of vanillin to vanillyl alcohol (Fig. 6). Multiple vanillic acid metabolic pathways have been described that include conversion through:

- (1) Hydroxylation of the carboxyl group to methoxyhydroquinone.
- (2) Demethylation of the methoxy group to protocatechuic acid.
- (3) Non-oxidative decarboxylation of the carboxyl group to guaiacol.
- (4) Reduction of the carboxyl group to vanillin.

The hydroxylation of vanillic acid to methoxyhydroquinone has been described in multiple ascomycete and basidiomycete fungi and appears to be most common metabolic pathway in fungi (Yajima *et al.*, 1979; Busswell and Eriksson, 1988; Guiraud *et al.*, 1992). A vanillate hydroxylase was isolated from *Sporotrichum pulverulentum* (an anamorph of *P. chrysosporium*) that uses NADH or NADPH as cofactor. However, the encoding vanillate hydroxylase gene remains to be identified. The demethylation of vanillic acid to protocatechuic acid was observed in many fungi such as *A. fumigatus*, *Aspergillus ultus*, *Doratomyces microspores*, *Penicillium hirsutum*, *Penicillium italicum*, *Penicillium roqueforti* and *P. chrysosporium* (Guiraud *et al.*, 1992). The decarboxylation of vanillic acid to guaiacol has been observed in *Aspergillus oryzae*, *Aspergillus parasiticus* and *Paecilomyces lilacinus* (Guiraud *et al.*, 1992). The fungal vanillic acid decarboxylase remains to be identified. Several fungi, such as *Aspergillus carbonarius*, *Trichoderma harzianum* and *Trichoderma reesei*, can reduce vanillic acid to vanillin and further to vanillyl alcohol (Guiraud *et al.*, 1992). In *Penicillium simplicissimum*, vanillyl alcohol is converted to vanillin by vanillyl alcohol oxidase (Vao) (de Jong *et al.*, 1990).

Benzoic acid

Two other aromatic compounds added to foods, beverages and cosmetics are benzoic acid (benzenecarboxylic acid) and the salt sodium benzoate. Benzoic acid has strong antimicrobial properties and is therefore mainly used in the food industry as preservative. Benzoic acid can also be used as pH adjuster and fragrance ingredient.

As mentioned previously, toluene, benzyl alcohol and benzaldehyde are converted to benzoic acid. Currently, only one benzoic acid metabolic pathway has been observed in fungi and was reported in *A. niger*, *A. nidulans*, *Cochliobolus lunatus*, *P. chrysosporium* and *Rhodotorula minuta* (Boschloo *et al.*, 1990; Fukuda *et al.*, 1996; Matsuzaki and Wariishi, 2005; Korošec *et al.*, 2014; Martins *et al.*, 2015). Benzoic acid is converted to *p*-hydroxybenzoic acid by benzoate monooxygenase (BphA) together with a NADPH cytochrome P450 reductase (CrcA) (van Gorcom *et al.*, 1990). *p*-Hydroxybenzoic acid is further converted to protocatechuic acid (3,4-dihydroxybenzoic acid) which is catalyzed by *p*-hydroxybenzoate-*m*-hydroxylase (PhhA) (Lubbers *et al.*, 2019b). The aromatic ring of protocatechuic acid is then cleaved by the protocatechuic 3,4-dioxygenase (PrcA) to 3-carboxy-*cis,cis*-muconic acid.

Cinnamic acid

Cinnamic acid is commonly used as flavor compound in foods and drinks, and for its aroma in perfumes and cosmetics. Cinnamic acid is naturally found in the spice cinnamon, which is derived from the bark of trees from the genus *Cinnamomum*. The main aromatic compound responsible for the flavor of cinnamon is cinnamyl aldehyde. Cinnamic acid also plays a role as the building block for lignin units and is synthesized from phenylalanine (Humphreys and Chapple, 2002). As mentioned above, microorganisms can also be exposed to cinnamic acid through lignin degradation and allelopathy.

Currently, three cinnamic acid metabolic pathways have been described in fungi. The most observed metabolic pathway in fungi is the decarboxylation of cinnamic acid to styrene and has been observed in multiple *Aspergilli* and the yeast *Saccharomyces cerevisiae* (Plumridge *et al.*, 2008; Mukai *et al.*, 2010). This conversion is catalyzed by cinnamic acid decarboxylase (CdcA) and the co-enzyme flavin prenyltransferase (PadA) (Plumridge *et al.*, 2008, 2010; Payne *et al.*, 2015; Lubbers *et al.*, 2019a). The deletion of *cdcA* or *padA* results in abolished growth on cinnamic acid (Lubbers *et al.*, 2019a). In addition, both are also essential for the degradation of sorbic acid, which is a commonly used food preservative. In the *A. niger* genome, between *cdcA* and *padA*, lies a transcriptional regulator known as the sorbic acid decarboxylase regulator (*sdrA*) (Plumridge *et al.*, 2008). This has been shown to regulate *cdcA* and *padA*, and deletion of *sdrA* results in reduced growth on cinnamic acid and sorbic acid (Lubbers *et al.*, 2019a).

Homologs of *cdcA*, *padA* and *sdrA* are clustered on the genome in several *Aspergillus* species. In the genome of *S. cerevisiae*, ferulic acid decarboxylase (*fdc1*) and *pad1* are next to each other, but no transcriptional regulator is located in between or next to them.

Two other cinnamic acid metabolic pathways have been suggested. The reduction of cinnamic acid to cinnamyl aldehyde and cinnamyl alcohol and was described for *A. japonicus* and the basidiomycete *Schizophyllum commune* (Milstein *et al.*, 1983; Nimura *et al.*, 2010). In *A. japonicus* and *A. niger*, the conversion of cinnamic acid to benzoic acid was suggested (Milstein *et al.*, 1983; Lubbers *et al.*, 2019b). Deletion of *bphA*, *phhA* or *prcA* in *A. niger* resulted in reduced growth on cinnamic acid indicating that cinnamic acid is converted through the benzoic acid metabolic pathway (Lubbers *et al.*, 2019b). It remains unknown which metabolic pathway is used for the conversion of cinnamic acid to benzoic acid in *A. niger*.

Conclusions and Future Prospects

The metabolism of aromatic compounds by fungi is interesting for several industries, since fungi can convert toxic compounds into harmless or valuable compounds. The study of fungal aromatic metabolism is important for applications where fungi can play a valuable role. For example, fungi can be used in the bioremediation of polluted environments or the biotransformation of aromatic compounds to chemical building blocks. Despite the genomic era in fungal research, many genes involved in the fungal aromatic metabolic pathways remain to be identified and this is essential for the genetic modification of fungi to create efficient strains.

Introduction

Filamentous fungi are a large group of eukaryotic organisms that have the ability to grow in many different environments, including biological wastes, soil, and plant and algal biomass. They also have the ability to grow on a wide variety of inexpensive substrates and produce a rich repertoire of interesting metabolites and enzymes, which has aroused considerable interest on the part of the scientific community for their exploitation as production organisms in biotechnology (Meyer, 2008). Nowadays, filamentous fungi are utilized as cell factories for the production of many industrially relevant compounds, such as organic acids, proteins, enzymes, exopolysaccharides, and secondary metabolites (Meyer, 2008; Nielsen and Nielsen, 2017) and fungi such as *Aspergillus niger*, *Aspergillus oryzae*, and *Trichoderma reesei* have become indispensable for enzyme production at industrial level (Frisvad *et al.*, 2018). Fungal enzymes currently make up more than half of the enzymes used in industrial applications (de Vries *et al.*, 2019), reflecting the importance of filamentous fungi as cell factories. In this context, one fundamental aspect for the future of fungal biotechnology is the improvement of production strains at the molecular level. Genetic engineering for strain improvement is a very powerful tool for increasing production levels, producing novel compounds and/or controlling/directing the synthesis of the desired products. Nevertheless, this will only be possible with the development of efficient methods to introduce (new) genes or control gene expression in filamentous fungi.

In this chapter, we summarize and discuss the currently available options for fungal transformation and genetic engineering of filamentous fungi.

Classical Genetic Engineering Approaches

Genetically Modified Strains (GMOs)

A genetically modified organism or strain (GMO) is defined as any (micro)organism whose genetic material has been modified through the application of genetic engineering methods. Genes can be transferred within the same species, across species, or even across kingdoms. Advances in the field of genetic engineering have allowed for precise control over the genetic changes introduced into an organism, overcoming the limitations of the naturally occurring genetic variation, thus optimizing the strain performance and/or improving the production of valuable substances. Despite gene transfer occur naturally between different species (horizontal gene transfer) (Gogarten and Townsend, 2005), there is a high social concern about the impact of GMOs in both human health and the environment. Unlike other methods for strain improvement, the application of genetic engineering technology is strictly regulated. Extensive legal framework on GMOs has been established in the European Union to protect human health and the environment (Directive, 2001/18/EC) and to ensure the free movement of safe and healthy genetically modified products in the market (Regulation (EC) No1829/2003). In the USA, GMO regulation is divided among three regulatory agencies: The Environmental Protection Agency (EPA), the Food and Drug Administration (FDA), and the US Department of Agriculture (USDA). The USA approach to regulate GMOs is premised on the assumption that regulation should focus more on the nature of the final products, rather than the process in which they were produced, making regulation of GMOs in the USA relatively favorable for their development compared to other countries.

Genetic Engineering of Filamentous Fungi

In practice, genetic engineering of filamentous fungi meets with several difficulties, since different transformation methods are required for the great diversity of fungal species with their very different and complex structures (Li *et al.*, 2017). In order to genetically modify filamentous fungi, first the genetic material needs to be introduced into the recipient cells with an efficient transformation method. Secondly, the genetic modification of interest needs to be integrated into the genome of the recipient strain. Finally, transformant strains need to be selected under certain selection conditions, which can vary depending on each fungal strain (Goosen *et al.*, 1987; Punt *et al.*, 1987; Olmedo-Monfil *et al.*, 2004). To date, several transformation methods have been described for filamentous fungi, including the commonly applied protoplast-mediated transformation and the *Agrobacterium*-mediated transformation methods, as well as electroporation, biolistics, and shock wave-mediated transformation.

Protoplast-mediated transformation

The introduction of the desired genetic modification in our fungus of interest often represents a challenge, since the establishment of a suitable and efficient transformation method is not trivial for many fungal species. The application of the protoplast-mediated transformation (PMT) has been extended to many filamentous fungal strains since the first successful transformation of the yeast *Saccharomyces cerevisiae* (Hinnen *et al.*, 1978), becoming one of the most commonly and routinely used methods for the

Fig. 1 Schematic representation of the basic steps for protoplast-mediated transformation.

transformation of filamentous fungi with high efficiency rates (Cantoral *et al.*, 1987; Dawe *et al.*, 2000; Meyer *et al.*, 2003). Protoplasts are cells from which the cell wall has been removed, usually by enzymatic digestion. The principle of PMT is to use commercially available cell wall-degrading enzymes to remove fungal cell wall components from either macroconidia, microconidia, or young mycelium to generate protoplasts, with the selection of a proper enzyme cocktail for the efficient protoplast formation (de Bekker *et al.*, 2009). Once formed, protoplasts are put into contact with the exogenous DNA of interest, which can be linearized or circular double-stranded DNA, and chemical reagents such as calcium ions and polyethylene glycol (PEG) are used to create small holes in the cell membrane and to promote the fusion of the exogenous DNA and the protoplasts, respectively (Li *et al.*, 2017). Finally, protoplasts are transferred to a selective medium (Fig. 1). Note that protoplasts are very sensitive to osmotic pressure, so it is necessary that a stable osmotic pressure is maintained to keep the protoplasts intact during the whole transformation process. Thus, osmotic stabilizers like sorbitol must be included in the buffers for protoplast generation to prevent cell damage. PEG also promotes cell agglomeration and together with the role described above, this makes PEG crucial for increasing transformation efficiency. Low transformation efficiencies can be in many cases improved by increasing the amount of PEG, and low molecular weight PEG (PEG3000, PEG4000 or PEG5000) is usually preferred over high molecular weight PEG (PEG8000) (Li *et al.*, 2017). Temperature also influences transformation efficiency. Normally protoplasts should be placed on ice, and the transformation process should be carried out at low temperature, although for some fungi such as *A. niger*, transformation at room temperature was demonstrated to also be very efficient (Kun *et al.*, 2020). PMT has been successfully applied in many ascomycete species such as *T. reesei* (Penttilä *et al.*, 1987; Gruber *et al.*, 1990), *Neurospora crassa* (Case *et al.*, 1979), many *Aspergillus* sp. (Tilburn *et al.*, 1983; Yelton *et al.*, 1984; Hahn and Batt, 1988; Meyer *et al.*, 2003; Storms *et al.*, 2005) and *Penicillium* sp. (Sánchez *et al.*, 1987; Itoh *et al.*, 1994; Fierro, 2004; Villarino *et al.*, 2018), and basidiomycetes, such as *Laccaria bicolor* (Kropp and Fortin, 1986), *Coprinus cinereus* (Binninger *et al.*, 1987), *Pleurotus ostreatus* (Peng *et al.*, 1993), *Trametes versicolor* (Bartholomew *et al.*, 2001) and *Dichomitus squalens* (Daly *et al.*, 2017).

Theoretically, any fungal species would undergo protoplast generation. However, for some particular fungi, such as the basidiomycete *Ustilago violacea*, protoplasts cannot be generated in high amounts or their quality is not good enough to undergo efficient transformation (Bej and Perlín, 1989; Ruiz-Díez, 2002). In these cases, the transformation of intact fungal cells could be an alternative. In this context, it is possible to induce cell permeability by using high concentrations of lithium acetate in combination with PEG, dithiothreitol (DTT), and/or dimethyl sulfoxide (DMSO) (Olmedo-Monfil *et al.*, 2004; He *et al.*, 2017). This method was applied in a few fungal species such as *N. crassa*, *Coprinus cinereus* or *U. violacea* (Olmedo-Monfil *et al.*, 2004), although its application is limited and alternative transformation methods with higher efficiency rates are preferred instead.

Agrobacterium tumefaciens-mediated transformation

Agrobacterium tumefaciens is a Gram-negative soil bacterium that naturally infects plants throughout pre-existing injuries. It carries a tumor-inducing plasmid (Ti plasmid) which contains the transfer DNA (T-DNA) flanked by two directional repeats (known as right and left borders), and the necessary genes (called virulence genes) to introduce this T-DNA randomly into the plant genome, causing the crown gall disease (Gohlke and Deeken, 2014). *A. tumefaciens* has been extensively studied as a biotechnological tool for the introduction of foreign genes into plants and fungi. In fungi, *A. tumefaciens*-mediated transformation (ATMT) was first applied in *S. cerevisiae* (Bundock *et al.*, 1995). For ATMT of filamentous fungi, a binary vector is designed in which the target gene is inserted between the right and left borders of the T-DNA, and is then transformed into the bacterium. Finally, *A. tumefaciens* is used as a vehicle to integrate the gene of interest into the fungal genome (Li *et al.*, 2017). The basic steps for ATMT of filamentous fungi are shown in Fig. 2. ATMT consists of three main successive steps: (1) *A. tumefaciens* culture induction with an inducing agent such as acetosyringone, (2) co-inoculation of the bacterium and fungal cells in solid medium containing filters, and (3) selection of the positive transformants with the appropriate selection pressure (Michiels *et al.*, 2005). Acetosyringone is an important agent for the transformation process, since it induces the expression of the virulence genes necessary for the T-DNA transfer to the fungal cells. Other important factors affecting ATMT efficiency are the co-culturing conditions (e.g., time, temperature, pH, filters), and should be empirically determined and optimized for each fungal strain (Li *et al.*, 2017).

ATMT has many advantages, since this method can be applied for protoplast, spores, germings, and/or hyphae transformation (Michiels *et al.*, 2005), and generates very stable transformants. In addition, ATMT leads to single-copy integration, in contrast to PMT, in which preferentially multi-copy integrations are observed (de Groot *et al.*, 1998; Meyer *et al.*, 2003). Currently ATMT is, together with

Fig. 2 Schematic representation of the basic steps for *Agrobacterium tumefaciens*-mediated transformation.

Fig. 3 Schematic representation of the electroporation-mediated transformation.

PMT, the method of choice for the transformation of many filamentous fungal species due to its high transformation rates and simplicity. ATMT has been successfully applied in a wide range of filamentous fungi, such as *Aspergillus giganteus* (Meyer *et al.*, 2003), *Botrytis cinerea* (Rolland *et al.*, 2003), *Fusarium oxysporum* (Mullins *et al.*, 2001), *Pyricularia* (*Magnaporthe*) *oryzae* (Rho *et al.*, 2001), *Aspergillus awamori*, *A. niger*, *N. crassa*, *T. reesei*, *Fusarium venenatum* (de Groot *et al.*, 1998), *Penicillium digitatum* (Wang and Li, 2008), *Penicillium expansum* (Zhang *et al.*, 2013), and in some basidiomycete and zygomycete species (Michielse *et al.*, 2005).

Electroporation-mediated transformation

Electroporation-mediated transformation (EMT) is a simple, fast, and efficient transformation method for both prokaryotic and eukaryotic cells (Haberl Meglič and Kotnik, 2017). This technology is based on the reversible capacity of cell membranes for permeabilization by short duration and high amplitude electric fields. After the application of the electric pulse, membrane permeabilization changes and pores can be formed, allowing the uptake of exogenous DNA into the cells (Fig. 3). After the electric shock, lipid and protein molecules in the biological membranes can restore their original structure, and DNA normally integrates into the genome, allowing the new traits to be inherited upon cell division. There are some factors that influence the efficiency of EMT, which include electric field intensity, variation in the electric charges (capacitance), pulse duration and frequency. However, the electric field intensity is the most important factor to control since high intensities correlate with higher rates of DNA uptake, but also with lower cell survival rates. For filamentous fungi, electric field magnitude ranges from 6 to 15 kV/cm and pulse width reaches the μ s-ms scale (Li *et al.*, 2017). Due to the large amount of heat produced during EMT, low temperature (4°C) is recommended during the transformation process. Compared to PMT and ATMT, this technology is simpler and involves fewer transformation steps. It is also fast, reproducible, and multiple copies of DNA can integrate into the genome, providing the potential for increased yields of the desired products. However, the electroporation mechanism is still unclear, and the difficulty for its optimization together with instrumental costs hinder its applicability in filamentous fungi. Nonetheless, EMT has been successfully applied in some fungal species such as *Penicillium urticae*, *A. oryzae*, *N. crassa* (Chakraborty *et al.*, 1991), *A. niger* (Ozeki *et al.*, 1994), *Monascus purpureus* (Lakrod *et al.*, 2003), *T. reesei* (Benocci *et al.*, 2018) and *Pseudogymnoascus verrucosus* (Díaz *et al.*, 2019).

Fig. 4 Schematic representation of the biolistics transformation.

Biolistic transformation

Biolistic transformation, also known as particle bombardment or gene gun, was initially described as an alternative to ATMT for the transformation of plant cells (Takeuchi *et al.*, 1992). For fungal transformation, either gold or tungsten particles are coated with foreign DNA, accelerated to a high speed, and bombarded towards spores or hyphae (Fig. 4) (Su *et al.*, 2012; Li *et al.*, 2017). As a result, both stable and/or transient transformations can occur. Transiently transformed cells are able to express the foreign DNA without integrating it into their genome, while stable transformed cells integrate the foreign DNA as part of their own genomic sequence. To date, many fungal species have been successfully transformed by biolistics, such as *Aspergillus nidulans* (Barcellos *et al.*, 1998), *T. reesei*, (Te'o *et al.*, 2002), *Trichoderma harzianum* (Lorito *et al.*, 1993), and some mycorrhizal fungi (Harrier and Millam, 2001). Biolistics is one of the most powerful genetic transformation technologies, since it is not subject to the limitations described for the other transformation methods, such as protoplast generation, or fungal cell wall composition. However, this methodology requires high instrumental and consumable investment, thus it is only considered to be applied for recalcitrant strains when other transformation methods were proved to work unsuccessfully (Li *et al.*, 2017).

Shock wave-mediated transformation technology

Shock waves have been widely applied in medicine to treat several diseases (Thiel, 2001). Some studies have revealed that shock waves cause transient cell permeabilization through acoustic cavitation, allowing large molecules such as DNA to enter and become trapped inside the cells (Gómez-Lim *et al.*, 2015). The Shock wave-mediated transformation technology (SWMT) was initially applied for bacterial transformation (Loske *et al.*, 2011), and later to filamentous fungi (Magaña-Ortíz *et al.*, 2013). In principle, a solution of fungal conidia together with exogenous DNA is placed in heat-sealed polyethylene bags. Then, bags are located inside the water tank of the shock wave generator. Samples are subsequently exposed to 50–400 shock waves generated at 7.5 kV at a rate of 0.5 Hz. Finally, conidia suspension is transferred to agar plates with cellulose filters for conidia regeneration, and after 24 h filters are transferred to fresh agar plates with a selective agent (Fig. 5) (Gómez-Lim *et al.*, 2015). SWMT shows some advantages compared to other transformation methods reported above, since shock waves can act directly on spores, and only a few parameters need to be controlled: spore/DNA concentration, energy, and speed of the shock waves (Li *et al.*, 2017). SWMT is efficient in filamentous fungi, and in some cases efficiency is higher than ATMT (Magaña-Ortíz *et al.*, 2013). Nevertheless, some limitations are impeding SWMT to become a widely applied transformation technology in microbiology laboratories, since shock wave sources and instruments are very expensive, and during the transformation process a great proportion of DNA can be damaged, thus decreasing transformation rates. However, it has been reported that genetic transformation can be enhanced when a second shock wave is sent shortly before bubbles are formed after the cavitation start to collapse, which is also known as tandem shock waves (Gómez-Lim *et al.*, 2015) compensating for the loss of good quality DNA.

Non-GMO Genetic Engineering Approaches

Random mutagenesis is a classical and successful method that relies on a trial-and-error process and has therefore been widely used for fungal strain improvement (Ribeiro *et al.*, 2013; Chand *et al.*, 2005). It consists of the application of a physical or chemical agent

Fig. 5 Schematic representation of the shock wave-mediated transformation technology.

Fig. 6 In random mutagenesis physical or/and chemical agents are applied to the parental strain to obtain a diverse population of mutants. These mutants are isolated and screened by different methods to obtain strains with improved characteristics of interest.

to the fungus that reacts with the DNA, producing different genetic mutations. When it occurs in nature, these mutations can lead to a high death rate, but also to a genetically more diverse population, affecting natural evolution. In biotechnological strain improvement, the resulting population is screened after the mutagenesis step with a specific method to detect strains that present the trait of interest (e.g., overproduction of a protein, improved thermostability of an enzyme, increased conversion of a substrate) (Fig. 6).

Organisms obtained by means of these “traditional” techniques are not subjected to the GMO regulation (Directive 2009/41/EC) and, therefore, the use and commercialization of these strains are easier as they require less strict containment and isolation measures.

The use of ultraviolet irradiation (UV) or chemical mutagenesis has the advantage that although a laborious work on screening a large number of strains is needed, it is not necessary to know the underlying mechanism why the mutation is effective. At the technical level, random mutagenesis is simple and can be effective even in non-domesticated species that are recalcitrant to targeted genetic manipulation (Tapia *et al.*, 2012). Some drawbacks compared to more targeted methods, such as site directed mutagenesis, are that additional genes can be affected, e.g., resulting in poorly growing strains, and that the genetic stability of the strains can be impaired, leading to genotypic and phenotypic changes in the following generations (Chand *et al.*, 2005). However, recent novel genomic tools have enabled more in-depth analysis of these randomly modified strains, providing new insights on the molecular mechanisms of many pathways and a better control on the safety and stability of the industrial strains (Nikolaev *et al.*, 2013).

UV mutagenesis

Ultraviolet (UV) light is the most used physical mutagenic agent for strain improvement. This method consists on the use of UVC radiation (~ 254 nm), which is also used for microbial disinfection, at a sublethal dose to modify the DNA structure by a photochemical reaction. This radiation excites the DNA molecule resulting in the formation of pyrimidine dimers between adjacent pyrimidines, which usually causes point mutations that can be incorporated into the genome if they are not repaired. These mutations are mainly base substitutions of cytosine (C) to thymine (T), but the effects of UV light can be more complex

(Ikehata and Ono, 2011). UV radiation presents a good cost-benefit relation compared to other physical mutagenic agents such as X-rays, γ -rays, or heavy ion beams, since UVC lamps are widely available and easy to handle (Tapia *et al.*, 2012). Radiation can be applied to mycelium or spores, and the dose conditions (intensity, time) need to be optimized (Jafari *et al.*, 2017).

UV mutagenesis can be performed alone, although it is often combined with other physical and/or chemical agents to widen the mutation type range and improve the efficiency (Bai *et al.*, 2004). Other physical mutagenic agents that have been used in strain improvement of filamentous fungi are X-rays, γ -rays, heavy ion beams, and low energy ion implantation. They have been developed in specialized facilities and allow a high mutation rate and wide range of mutation types compared to UV, although they are not discussed here in detail (Jin *et al.*, 2017; Awan *et al.*, 2011; Hu *et al.*, 2014; Zhao *et al.*, 2012).

One of the most widely used strains of filamentous fungi for cellulase production, *T. reesei* RUT-C30, was obtained by three rounds of UV and chemical mutagenesis with a very thorough screening process focused on high production of cellulases and catabolite de-repression. This mutant produced approximately 20 mg of extracellular protein per ml, which represents a 15- to 20-fold increase in secreted protein compared to the original strain when grown in flasks (Peterson and Nevalainen, 2012). Mutagenesis by UV irradiation also resulted in a mutant with higher cellulase activity (71 units/ml) compared to the wild type strain (53.7 units/ml) in *A. niger* (Shafique *et al.*, 2009).

A classic example of UV mutagenesis application in *A. niger* is the isolation of protease deficient mutants that are valuable in protein production applications as they show a reduced level of extracellular protein degradation (Mattern *et al.*, 1992). In the case of metabolite production, a L(+) -lactic acid over-producing *Rhizopus oryzae* mutant was isolated by combination of UV, diethyl sulfate (DES) and ^{60}Co mutagenesis that produced 79.4 g/l L(+) -lactic acid, 52% more than the parent strain (Bai *et al.*, 2004).

Chemical mutagenesis

Intercalating molecules such as ethidium bromide interact with the DNA by inserting themselves between the base pairs and stretching the DNA strand. This can cause the DNA polymerase to insert an extra nucleotide in the opposite strand, resulting in a frameshift mutation when the modification is replicated (Ferguson and Denny, 2007).

Other common DNA reacting molecules that have been used as mutagenic agents for strain engineering are alkylating agents, such as N-methyl-N'-nitro-N-nitrosoguanidine (NTG), ethylmethane sulfonate (EMS), and 1-methyl-3-nitro-1-nitrosoguanidine (MNNG). These mutagens add an alkyl group to nucleotides which may result in a transition mutation where one pyrimidine of purine base is substituted by the other (Leitao, 2012). For instance, EMS was used for the improvement of an *Ashbya gossypii* strain for heterologous production of *T. reesei* endoglucanase I (EGI), and other cellulase-active native enzymes, achieving 2- to 3-fold improvements in the measured activities (Ribeiro *et al.*, 2013).

Combined use of mutagenesis approaches

As mentioned above, chemical agents are often used in combination with physical agents, such as UV irradiation, or other chemical agents for strain improvement. Mutagenesis by UV irradiation and NTG has been widely used due to its simplicity. The examples range from improving wild species for pectinase production in food industry (Huang *et al.*, 2019) to cellulases that are used in biomass treatment by various industries (Xu *et al.*, 2011). As an example, the combined use of UV radiation with NTG or ethidium bromide in *A. oryzae* achieved a mutant with 4-fold higher cellulase activity than the wild type strain (El-Ghonemy *et al.*, 2014).

Techniques with a high mutation rate like γ -rays can be used not only for improving the production of an enzyme of interest, but also to screen for an improved characteristic on this enzyme. For example, to improve thermal stability of α -amylases for maltose sirup production in *A. oryzae* (Aleem *et al.*, 2018). In this study, a 5-step screening process was needed to find the mutants that produced the thermoresistant enzyme in high amounts (Aleem *et al.*, 2018). A combined use of ^{60}Co γ -rays, UV irradiation, and NTG has also been applied in other *Aspergillus* sp. (Vu *et al.*, 2011).

Combined mutagenesis has also been applied in pharmacology. As an example, *Aspergillus fumigatus* and *Alternaria tenuissima* that naturally produce the anticancer drug Paclitaxel were subjected to UV and γ -irradiation mutagenesis in order to improve their producing ability. In this study, two stable strains were identified, with Paclitaxel titers that were 1.22 and 1.24-fold higher compared to the parental strains (El-Sayed *et al.*, 2019). In the fungus *F. oxysporum*, two rounds of nitrosoguanidine mutagenesis together with optimization of the medium conditions helped to increase the antibiotic enniatin production 3-fold with respect to previous studies with submerged cultures (Madry *et al.*, 1983). Random mutagenesis is useful not only for improving the yield of a product, but also for improving the use of a specific substrate. In this context, the production of citric acid, an important biotechnological product for food and other industries, using black molasses as substrate was improved by UV followed by NTG mutagenesis from 31.1 g/l in the parental strain to 50.0 and 86.1 g/l in the most productive mutants (Ikram-Ul-Haq *et al.*, 2001).

Adaptive evolution

The main disadvantage of chemical and UV mutagenesis is the occurrence of random non-desired mutations that could have a negative effect on the performance of the strain in process conditions. In recent years an alternative, non-GMO, methodology has been developed, called adaptive evolution. This method is based on the principle that random mutations occur continuously in fungal genomes and that only those that are advantageous will be able to persist in a population. In fact, if the advantage of the mutation is significant, only individuals that contain this mutation will ultimately survive in a fungal culture. Therefore, a crucial step of this approach is the design of conditions under which strains with the desired mutation(s) have a competitive advantage to those lacking them, enabling them to outcompete the non-mutated strains.

Adaptive evolution was initially applied in the yeast *S. cerevisiae* to improve co-fermentation of glucose and xylose to ethanol (Sonderegger and Sauer, 2003). In filamentous fungi only few examples of adaptive evolution have been reported. Improvement of growth at 37°C was achieved through adaptive evolution in *Metarhizium anisopliae* (de Crecy et al., 2009). In *A. niger*, selection for improved growth on cellulose resulted in a strain that produced higher levels of enzymes degrading cellulose (Patyshakuliyeva et al., 2016). Transcriptome analysis demonstrated that this was due to the loss of expression of a gene that was shown to encode a repressor of cellulolytic genes in *Podospora anserina* (Brun et al., 2009). In the same species, growth on increasing levels of ferulic acid resulted in a strain with a higher tolerance to aromatic compounds, which was shown to be due to an increase in aromatic metabolism (Lubbers et al., 2020). In *A. oryzae*, repeated inoculation on inulin containing plates resulted in a strain with increased exo-inulinase activity, but also increased activities of other plant biomass degrading enzymes (Culleton et al., 2016). The molecular basis of this mutant has not yet been identified.

Despite the limited examples, the success of this method implies that it is suitable for a much broader set of applications. As only mutations that provide a benefit to the desired phenotype are enriched, this method results in less non-desired mutations than UV or chemical mutagenesis.

Novel Strain Engineering Approaches

The discovery of transformation procedures in the 1980s, the development of molecular tools for the modification of DNA in fungal genomes (e.g., homologous recombination), the current availability of a large number of fungal genomic sequences, and the development of novel genome editing methodologies have strongly expanded the toolkit for fungal strain engineering, enabling the generation of fungal strains with commercially valuable properties with high level of control of the strain modifications. In recent years, highly precise genome editing systems have revolutionized fungal biotechnology and broadened the range of modifications that can be performed at a target genetic locus, thus resulting in an endless number of possibilities of genomic modifications for strain improvement.

CRISPR/Cas Technology

The type II Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR)/CRISPR-associated protein (Cas) system originated from archaeal and bacterial adaptive immune systems (Jinek et al., 2012), and has revolutionized high-throughput functional genomics. The CRISPR/Cas9 genome editing system contains two main components: the Cas9 endonuclease, and an easily customizable single guide RNA (sgRNA) formed by the fusion of the CRISPR RNA (crRNA) and trans-activating RNA (tracrRNA) (Brouns et al., 2008; Deltcheva et al., 2011). In order to induce genomic modifications, 20 nucleotides of the sgRNA target the genomic DNA via homology base pairing. Subsequently, Cas9 endonuclease binds to the target DNA through the interaction with the Protospacer Adjacent Motif (PAM) located immediately downstream of the target 20-bp genomic sequence. After binding, Cas9 will induce a double strand break (DSB) three nucleotides upstream of the PAM (Garneau et al., 2010), which is detected as potentially lethal damage and needs to be repaired to ensure the survival of the organism (Fig. 7). In eukaryotic systems like filamentous fungi, there are two natural DNA repair mechanisms that allow DSB repair: the error-prone non-homologous end-joining (NHEJ) and high-fidelity homology-directed repair (HDR) pathways. With NHEJ, DNA breaks are directly re-ligated by the Ku70 and Ku80 heterodimeric complex, frequently leading to imprecise DNA repair and loss of genetic functionality (Davis and Chen, 2013). In contrast, HDR only occurs in the presence of a homologous duplex DNA template (referred as rescue template, RT) via homologous recombination (Liu et al., 2018; Wright et al., 2018), which can be used to precisely introduce the DNA sequence of interest in the target organism (Fig. 7).

Streptococcus pyogenes SpCas9 protein is the preferred Cas nuclease to date due to the abundance of its target PAM sequence (5'-NGG-3') within genomes (Jinek et al., 2012), which opens the door to an endless number of possibilities for genome editing, but also increases the probability of unintended mutations. Alternative CRISPR/Cas systems have been developed in order to overcome this limitation, including highly specific engineered Cas9 variants (e.g., eSp-Cas9, SpCas9-HF, or PAM-altered SpCas9), Cas9 homologs derived from other bacteria with different PAM specificities and sgRNA structures, and novel Cas proteins different from Cas9 (e.g., Cpf1, C2c2) (Nakade et al., 2017).

In some cases, the introduction of a single genomic modification is not enough to improve a strain for industrial purposes, and editing of multiple traits is required to fine-tune metabolic networks of potential fungal cell factories. One possibility of introducing multiple genomic modifications with CRISPR/Cas is to perform iterative rounds of genome editing by recycling or using different selection markers. However, the multiplexing capabilities of this system for the introduction of multiple traits at the same time are currently being exploited with both Cas9 and more recently Cpf1 (also known as Cas12a), whose crRNA structure and processing activity increases the simplicity of multiplexing compared to Cas9 crRNA (Adiego-Pérez et al., 2019).

The first application of the CRISPR/Cas9 technology in filamentous fungi was in the industrially relevant *T. reesei* (Liu et al., 2015) and in six different *Aspergillus* species (Nødvig et al., 2015). Nowadays, the CRISPR/Cas9 system enables the genetic improvement of a wide variety of filamentous fungal species, including *P. oryzae* (Arazoe et al., 2015a), *N. crassa* (Matsu-Ura et al., 2015), *A. oryzae* (Katayama et al., 2016), *A. fumigatus* (Zhang et al., 2016), *Penicillium chrysogenum* (Pohl et al., 2016), *Alternaria alternata* (Wenderoth et al., 2017), *Beauveria bassiana* (Chen et al., 2017), *F. oxysporum* (Wang et al., 2018b), *Fusarium solani*

Fig. 7 Schematic representation of the CRISPR/Cas9 system. Double strand breaks (DSBs) induced by Cas9 can be repaired by two pathways. In the error-prone Non-Homologous End Joining NHEJ pathway, DSB are processed by endogenous DNA repair machinery, which may result in random mutations. Alternatively, a rescue template can be supplied to trigger the Homologous Directed Repair (HDR) pathway, which allows precise gene editing.

(Lightfoot and Fuller, 2019), *Fusarium fujikuroi* (Shi *et al.*, 2019) and *Penicillium subrubescens* (Salazar-Cerezo *et al.*, 2020) with different mutation efficiencies. Alternatively, CRISPR-Cpf1 has also been applied in some fungal species with high efficiency rates, such as *S. cerevisiae* (Li *et al.*, 2018) and the filamentous fungi *A. nidulans*, *A. niger* (Vanegas *et al.*, 2019), *Thermothelomyces thermophilus* (Kwon *et al.*, 2019) and *A. gossypii* (Jiménez *et al.*, 2019).

Other Novel Strain Engineering Approaches

Although CRISPR/Cas is becoming one of the most applied genome editing technologies for strain improvement, there are other valuable genome editing strategies that expand the toolbox for genetic engineering of filamentous fungi.

Zinc fingers (ZFs) are small proteins that have the ability to bind DNA through specific alpha helical protein motifs and have been adopted as gene-targeting tools. Naturally, each alpha helix of a ZF shows a unique amino acid sequence that interacts specifically with its corresponding DNA sequence. For strain engineering, ZFs are used as substrate for binding DNA, and are coupled with a restriction endonuclease (Zinc-finger nuclease, ZFN) to induce DSBs in the target DNA sequence (Carroll, 2011; Palpant and Dudzinski, 2013).

Transcription activator-like effector (TALE) nucleases (TALENs) also allow site-specific DNA DSBs, making them a valuable tool for strain improvement in many organisms, including filamentous fungi. TALE binding to DNA is mediated by a central region of these proteins that contains around 30 tandem repeats of 33–35 amino acids (Christian *et al.*, 2010). The amino acid sequence of each tandem repeat is invariant, except for the two adjacent amino acids (referred as repeat variable residue, RVD). Repeats with different RVDs recognize distinct DNA base pairs, allowing the development of this technology for directed mutagenesis when fusing customized TALE to endonucleases (e.g., Fok-I) that cut the target DNA, triggering the DSBs DNA repair pathways (Jiang *et al.*, 2013). TALENs has been successfully applied in several filamentous fungi such as *P. oryzae* (Arazoe *et al.*, 2015b), *A. oryzae* (Mizutani *et al.*, 2017), and *T. reesei* (Liu *et al.*, 2017b).

Even though these novel genome editing techniques allow the generation of specific genomic alterations more precisely than random mutagenesis techniques, in July 2018, the European Court of Justice ruled that (micro)organisms generated by directed mutagenesis techniques, such as CRISPR/Cas, ZFNs or TALENs require the same treatment as any other GMO in the European Union (Directive 2001/18/EC). In this context, meeting the obligations of the GMO Directive implies cost- and labor-intensive pre-market evaluations and long approval processes, which may decrease investments, and limit research and commercialization.

Applications of Strain Improvement

Filamentous fungi play a very important role in the production of biotechnologically interesting compounds, such as organic acids (Dörsam *et al.*, 2017), enzymes degrading complex plant biomass (de Vries, 2003), and drugs such as penicillin and other antibiotics (Brun *et al.*, 2009). Very often, wild-type strains do not produce these compounds at levels required in industry, or do not produce the desired proteins with the required properties or catalytic specificity. To overcome these problems, different genetic engineering approaches have been developed in order to improve the industrial potential of filamentous fungi for industrial applications.

Gene Overexpression

Gene overexpression is a procedure which leads to increased target gene expression for different purposes. In strain engineering of filamentous fungi, this approach is very useful for increasing the production of a protein or enzyme of interest. Overexpression of specific enzymes can increase the production of a metabolite of interest, or the conversion of a substrate. Moreover, the production of metabolites or proteins can be achieved indirectly by the overexpression of the regulators that control the expression of the involved genes or pathways. In the following sections, different gene overexpression strategies are described.

Replacing the promoter

Promoters drive the expression levels of genes and determine how this expression is affected by the activators and repressors of the regulatory system. There are constitutive promoters that are active independently of the environmental or internal signals, which typically drive the expression of housekeeping genes. Conversely, there are promoters that are controlled by transcription factors based on the environmental signals, for example, catabolic enzymes (Vogl and Glieder, 2013). To improve the production of a specific protein, the promoter of the corresponding gene can be switched for one with stronger expression, and, to improve the expression of a set of related genes of interest (e.g., biosynthetic or catabolic cluster), it may be possible to overexpress the transcription factor(s) controlling their expression (Gao *et al.*, 2017). Overexpression of genes can lead to overburdening of the cellular mechanisms or accumulation of toxic metabolites, which can be detrimental to the cell. As a solution to this, inducible promoters can be interesting tools to control gene expression in time. In the case of intermediate accumulation, this may happen because the enzymes in the pathway are expressed in different ratios than in the natural stoichiometry, and therefore some metabolites can accumulate due to limited enzymatic activity in the next step. This can be avoided by balancing the expression of the enzymes with specific promoters to mimic a more natural stoichiometry (Vogl *et al.*, 2018).

Regarding specific examples, the cellobiohydrolase I (*cbh1*) gene promoter, which is induced in the presence of cellulose, is often used in *T. reesei* and other fungi specially for heterologous protein production (Nevalainen and Peterson, 2014). Moreover, in *T. reesei*, this promoter has been optimized for improving the efficiency by replacing the negative regulator binding sites for positive regulator binding sites, demonstrating improved expression levels of heterologous genes (Liu *et al.*, 2008; Zou *et al.*, 2012).

In *Aspergillus* sp. there are several well-characterized promoters for high gene expression that can be used in the original organism or in different fungi. The most commonly used ones are the glucoamylase promoter (*PglaA*) from *A. niger*, the glyceraldehyde-3-phosphate dehydrogenase promoter (*PgpdA*) from *A. nidulans* and the Taka-amylase A promoter (*PamyB*) from *A. oryzae* (Xie *et al.*, 2020). For instance, the *PadhA* promoter from *A. nidulans* was introduced in *Aspergillus terreus* to overexpress acetyl-CoA carboxylase in order to increase the production of the cholesterol lowering agent lovastatin (Hasan *et al.*, 2018). Some efforts have been made for the production of the organic acid L-malate directly from corn starch in order to avoid the saccharification step. To engineer this metabolic pathway in *A. oryzae*, the *PglaA* promoter and an engineered version of this one (PN5) were used to simultaneously overexpress three key enzymes, improving the L-malate titer from 55.5 to 78.5 g/l (Liu *et al.*, 2017a).

As an alternative to the use of known heterologous promoters, novel strong promoters of a specific strain can be detected by transcriptomic analysis, where the highly expressed genes may provide these kind promoters (Hu *et al.*, 2015; Wang *et al.*, 2018a).

Histone-encoding genes are highly expressed for the synthesis of DNA during the cell cycle. The activation of these promoters depends on the cell cycle stage, and the asynchronic growth of protein producing cultures may affect the promoter efficiency. At any specific time point, different cells are in different stages of their cell cycle, and therefore, while many of them will be highly expressing the gene, some may not, but the overall result is a constitutive and high expression of homologous and heterologous genes (Belshaw *et al.*, 2002). *Mortierella alpina* is an oil producing filamentous fungus of interest for nutrition and pharmacology industries as its biomass can consist of up to 50% triacylglycerol. The malic enzyme catalyzes the oxidative decarboxylation of L-malate to pyruvate and has been suggested to be important during fatty acid synthesis in oleaginous fungi as a NADPH-supplying enzyme. By introducing a construct of the malic enzyme encoding gene driven by the homologous histone H4.1 promoter, the content of arachidonic acid was increased 60%, without altering the total fatty acid content (Hao *et al.*, 2014).

Homologous recombination and gene editing tools can be applied to replace the endogenous promoter of the gene of interest by a stronger one, avoiding problems of random and multi-copy insertion of the construct. By using the CRISPR/Cas9 system in *N. crassa* it was possible to switch the endogenous cellulase regulator *clr-2* promoter for the β -tubulin constitutive promoter, achieving a higher cellulase production (Matsu-Ura *et al.*, 2015). These tools allow not only the replacement of the promoter but also the insertion of directed point mutations, where the characteristic modifications of hyper-producing mutants can be emulated. The implementation of this strategy in *A. niger* demonstrated that the mutation W361R in the transcription factor GaaR, found in a UV mutant, was responsible for constitutive pectinases production (Alazi *et al.*, 2018b).

As mentioned before, there are several examples of increasing the production of a set of proteins by overexpression of their regulator. The xylanolytic regulator Xyr1 of *T. reesei* induces the production of different cellulolytic and hemicellulolytic enzymes. Expression of the *xyr1* gene is induced in the presence of lactose and cellulose and controlled by carbon catabolite repression (Benocci *et al.*, 2017). By overexpressing this gene by switching the native promoter with a different promoter, either a constitutive (Wang *et al.*, 2013) or an inducible one (Lv *et al.*, 2015), cellulolytic enzyme production can be significantly increased independently of the induction conditions. Another example of overexpression of a regulator is the transcription factor encoding gene *gaar* in *A. niger* that resulted in increased production of pectinases independently of the presence of the inducer D-galacturonic acid (Alazi *et al.*, 2018a).

An alternative kind of promoters are bidirectional promoters, which allow the expression of two genes at the same time, for instance, the gene of interest and the selection marker, two copies of the gene of interest, or different genes. Recently, natural bidirectional promoters have been found in filamentous fungi for various applications. The histone H4.1 and H3 promoters can act as natural bidirectional promoters that allow simultaneous expression of enzymes in the case of metabolic engineering in *Aspergillus* sp. (Rendsvig *et al.*, 2019). Interestingly, some inducible promoters such as *A. niger* D-galacturonic acid reductase promoter, show a bidirectional transcription, and can be used as bidirectional and inducible promoters (Kuivanen *et al.*, 2015). In this study, enzymes from the plant L-ascorbic acid pathway were introduced in *A. niger* for improving plant biomass D-galacturonic acid conversion to L-ascorbic acid, achieving titers up to 170 g/l.

Increasing the gene copy number

Increasing the copy number of a gene can increase significantly protein production, and this technique has been commonly used in fungal strain improvement (Archer *et al.*, 1994). This strategy has been used for example in the production of penicillin by *P. chrysogenum*, by inserting multiple copies of the penicillin biosynthesis cluster in the genome (van den Berg, 2010).

A high copy number can be achieved by (1) adding high amounts of DNA during transformation, using multiple constructs with different selection markers, (2) applying a strong antibiotic pressure, either by adding a high concentration or using a weak promoter for the selection marker, or (3) using bidirectional promoters, which would allow the transcription of two copies of the gene in the same construct. Increasing the number of copies can compromise the stability of the strain, which is especially undesired in industry where prolonged cultivation of strains is needed (Deckers *et al.*, 2020).

In some studies, depletion of transcription factors due to multicopy insertion of the gene of interest under the control of the same promoter has been detected. To avoid this, the possibility of inserting the gene under the control of different promoters that are induced under the same conditions has been explored (Miyauchi *et al.*, 2013).

Gene Downregulation

Gene downregulation can be defined as a genetic engineering approach in which one target gene of interest is made inoperative in an organism. Gene downregulation is a key approach to study gene function and to alter the characteristics of a fungal strain for different applications, such as improving enzyme production by the inactivation of repressor-encoding genes (Ichinose *et al.*, 2018), the inactivation of genes that results in increased gene recombination frequencies for subsequent transformations, or for the reduction of byproduct formation (Meyer, 2008). For this aims, genes can be either (partially) deleted, mutated, or silenced in filamentous fungi (Khan *et al.*, 2014).

Gene deletion

Gene deletion or gene knockout (represented with Δ) is a type of mutation that involves the total inactivation of a gene of interest through the loss of genetic material, and has been widely used to attribute physiological functions to a gene of interest by phenotype correlation after (partial) gene elimination.

Gene deletions can be applied for strain improvement in filamentous fungi. One of the main drawbacks for strain improvement of filamentous fungi is the low frequency of gene integrations into the genome, since DNA integration is mainly directed by NHEJ (Kuck and Hoff, 2010). To solve this problem, defective strains in NHEJ with improved site-specific recombination have been constructed in many fungal species by deletion of the Ku70 or Ku80-encoding genes, as for example *Neurospora* (Ninomiya *et al.*, 2004), *A. nidulans* (Szewczyk *et al.*, 2006), *A. oryzae* and *Aspergillus sojae* (Takahashi *et al.*, 2006), *Claviceps purpurea* (Haarmann *et al.*, 2008), *M. oryzae* (Villalba *et al.*, 2008), *Penicillium decumbens* (Li *et al.*, 2010), and *P. digitatum* (Gandía *et al.*, 2016).

Gene deletion approaches have also allowed the construction of gene knockout libraries in fungal species like *Aspergillus* and *Neurospora*, resulting in the identification of genes encoding novel transcription factors which are involved in the production of industrially relevant enzymes such as cellulases (Colot *et al.*, 2006; Ogawa *et al.*, 2013). Deletion of several transcription factor-encoding genes in some filamentous fungi can also result in an increased production of specific enzymes. For example, double deletion of the negative regulators CreA and CreB-encoding genes *creA* and *creB* in *A. oryzae* resulted in an increase of plant biomass degrading enzyme production such as α -amylases, xylanases and β -glucosidases (Ichinose *et al.*, 2018). In *T. reesei*, deletion of the cellulase and xylanase negative regulator encoding gene *ace1* increased gene expression in the presence of cellulose or the inducer sophorose (Aro *et al.*, 2003). In *P. anserina* and *A. niger*, the regulator NoxR was shown to negatively affect cellulase production, since Δ noxR mutants were able to degrade cellulose more efficiently than the parental strain (Brun *et al.*, 2009; Patyshakuliyeva *et al.*, 2016).

Gene knockout strategies have also enabled improved production of interesting metabolites and inhibition of toxic metabolites in filamentous fungi by genetic engineering of metabolic genes. For instance, deletion of L-galactonic acid dehydratase-encoding genes *gaaB* and *lgd1* in *A. niger* and *T. reesei*, respectively, increased extracellular accumulation of L-galactonic acid, with potential applications in the pharmaceutical, cosmetic, and many other industries (Kuivanen *et al.*, 2012). In *Myceliophthora thermophila*, multiple deletion of two fumarate reductase and a mitochondrial fumarase-encoding genes increased production of fumaric acid that is widely used in the food and pharmaceutical industries (Gu *et al.*, 2018). In *P. decumbens* and *Penicillium oxalicum*, deletion of *bgl2*, the major intracellular β -glucosidase encoding gene, resulted in significantly improved cellulase production (Chen *et al.*, 2013; Yao *et al.*, 2015). On the other hand, deletion of each of the fifteen genes involved in patulin biosynthetic pathway resulted in decreased (or abolished) ability of *P. expansum* to produce patulin, a mycotoxin that is often present as a contaminant in food, particularly in fruits and fruit-derived products (Li *et al.*, 2019).

Gene deletions can also be applied in many different plant and human pathogenic fungi in order to decrease their pathogenicity and/or virulence for different applications. For example, deletion of Mitogen-Activated Protein Kinases (MAPK)-encoding genes such as *slt2* or *kss1* in the phytopathogenic fungus *P. digitatum* resulted in strong reduction on virulence during infection on citrus fruits, which can be very interesting for the control of citrus postharvest diseases (Gandía *et al.*, 2019). Similarly, deletion of lipase-encoding genes *CpLIP1* and *CpLIP2* highly reduced virulence in the relevant human pathogen *Candida parapsilosis* (Gácsér *et al.*, 2007), opening the door for the development of new antimycotic drugs.

Point mutations

Gene inactivation can also involve single missing DNA base pairs and single nucleotide changes. Point mutations can have a wide variety of consequences, ranging from no effect (synonymous or silent mutations) to amino acid changes (missense mutations or frameshifts) and the apparition of premature stop codons (nonsense mutations). In many cases, mutations can be harmful for the organisms or decrease their capability to be used as efficient cell factories. One example of a loss of gene functionality with negative consequences in filamentous fungi is the loss of sorbicillinoids production capability in *P. chrysogenum*, which are interesting secondary metabolites with antiviral, anti-inflammatory, and antimicrobial activities, due to a point mutation acquired in the *sorA* gene, which encodes for a polyketide synthase (Salo *et al.*, 2016). Another example is the non-citric acid production phenotype of a UV-derived *A. niger* mutant caused by a point mutation in *laeA* gene, encoding a putative methyltransferase-domain protein (Bok and Keller, 2004). However, certain mutations can make the organisms adapt better to the environment and improve their (biocatalytic) performance.

Point mutations for fungal strain improvement have been typically achieved by the application of physical and chemical mutagenesis (Parekh *et al.*, 2000). However, the new DNA-editing technologies such as CRISPR/Cas allow the precise (on-site) introduction of targeted point mutations in a more efficient and controlled way in filamentous fungi (Kun *et al.*, 2020). In the white-rot basidiomycete fungus *Pleurotus ostreatus*, a novel selection marker gene for transformation was developed by introducing a point mutation in a gene that encodes the iron-sulfur protein subunit of a succinate dehydrogenase (Honda *et al.*, 2000). Point mutations also resulted in improved cysteine biosynthesis in *Penicillium rubens* by the inactivation of enzymatic conversions that compete with the cysteine biosynthetic pathway, which plays a key role in penicillin production (Wu *et al.*, 2020). In addition, many *T. reesei* strains highly used at industrial level underwent point mutations leading to catabolite derepression, resulting in increased extracellular enzyme and protein levels compared to their wild type strain (Bischof *et al.*, 2016).

These examples demonstrate a wide range of possibilities of point mutations for gene inactivation and strain improvement in filamentous fungi. However, complete gene deletions by means of homologous recombination are still the preferred genetic engineering mechanisms to generate knockout strains throughout the scientific community.

RNA interference (RNAi)

The possibility to inactivate a given gene or metabolic pathway is not only restricted to DNA-based approaches. RNA interference (RNAi) is a mechanism for gene silencing/inactivation that represses gene expression by means of small non-coding RNAs (sRNAs) in eukaryotic organisms (Nicolás and Garre, 2017). In filamentous fungi, the gene silencing effects triggered by RNAi were firstly observed in *N. crassa*, a phenomenon that was initially called Quelling (Romano and Macino, 1992). The RNAi mechanism is highly conserved in the fungal kingdom, and is basically driven by two main components: a double-strand RNA endonuclease (Dicer), and a small RNA-binding protein (Argonaute). Dicer cleaves double strand RNAs (dsRNA) to generate sRNAs from 20 to 30 nucleotides that are subsequently carried by Argonaute and used to identify complementary sequences, triggering the degradation of the target sequences (Billmyre *et al.*, 2013).

RNAi is involved in a broad spectrum of biological functions, such as genome defense against virus or transposon invasion. However, this mechanism has been adapted as a potential biotechnological tool to improve fungal strains in different ways. For instance, RNAi was used to attenuate the expression of the *creA* gene in *P. chrysogenum*. Transformants expressing sRNA targeting *creA* showed increased penicillin production (Cepeda-García *et al.*, 2014). In *A. oryzae*, RNAi-based inactivation of three α -amylase-encoding genes improved heterologous protein production in the culture media (Nemoto *et al.*, 2009). Similarly, suppression of the expression of a cellobiohydrolase-encoding gene (*cbh1*) in *T. reesei* by RNAi increased gene expression of a heterologously expressed lipase-encoding gene from *A. niger* (Qin *et al.*, 2012).

Compared to conventional gene knockout strategies, such as gene deletion by homologous recombination, RNAi has potential advantages. One advantage is its applicability to inactivate gene expression regardless gene targeting efficiency, since the efficiency of homologous recombination varies among fungal species. In addition, RNAi is very convenient when multiple copies of a gene

of interest are present in the genome. Moreover, the function of essential genes in biological processes remains unknown since classical genetic approaches such as gene deletion are not available due to lethality. In this context, RNAi can be used for analyzing lethal genes since it mostly induces knock-down of gene expression but not complete knockout (Nakayashiki, 2005). However, potential disadvantages of RNAi-based gene silencing are the incomplete reduction of the gene expression, and the instability of the transformants (Henry *et al.*, 2007).

Conclusions and Future Prospects

Genetic engineering of filamentous fungi has been an established approach in biotechnology, affecting processes in many industrial sectors. Non-GMO approaches have the widest applicability as they are not subject to GMO regulations that limit the use of GMO-based approaches in many applications. These regulations differ globally, with e.g., the USA allowing a broader application of GMO strains than the EU. The recent development of novel genome editing technologies, such as CRISPR/Cas9, that enable genetic engineering without the introduction of foreign DNA and without easy trackability has re-activated the discussion on GMO regulations and may open the door for a broader application of these technologies.

The global switch to a sustainable biobased economy provides many opportunities for fungi due to their high ability to convert plant biomass to a wide range of products. Fungal fermentations have the potential to replace many chemical processes that are based on fossil resources, but natural fungal isolates are unlikely to be efficient enough to result in economically sustainable processes. Genetic engineering will be needed to improve the productivity of fungal cell factories, reduce the production of side-products and increase the tolerance of the selected fungi to the process conditions. After the genomics era in fungal research, the coming decade(s) may well become the era of fungal cell factories.

Introduction

The filamentous fungi *Trichoderma* spp. (Hypocreales, Ascomycota) have been widely studied for their application in industry, agriculture, and other areas. For industrial applications, the well-known species *T. reesei* has been used almost exclusively for producing cellulolytic and hemicellulolytic enzymes and heterologous proteins. This is because enzymatic hydrolysis is considered a more commercially and environmentally beneficial procedure than chemical hydrolysis (Druzhinina and Kubicek, 2016; Payne *et al.*, 2015). In agriculture, highly mycoparasitic strains from several species such as *T. atroviride*, *T. virens*, *T. asperellum*, and *T. harzianum* have been used as bioeffectors in commercial formulations for the biological control of fungal pests (biocontrol). Some of these species can colonize root surfaces and elicit a plant defense response to different pathogenic fungi while simultaneously stimulating plant growth (Harman *et al.*, 2004; Druzhinina *et al.*, 2011). Moreover, *Trichoderma* spp. prolifically produce bioactive secondary metabolites; many of which have already been utilized as fungicides or plant growth-promoting agents, while others have the potential for application in the pharmaceutical industry (Contreras-Cornejo *et al.*, 2016; Keswani *et al.*, 2014; Zeilinger *et al.*, 2016).

Modifying particular genes in *Trichoderma* will enhance their abilities, such as those described above, for better application purposes. Several gene modification approaches have been used in filamentous fungi to obtain enzyme hyper-producers (Druzhinina and Kubicek, 2016; Mei *et al.*, 2019; Shi *et al.*, 2017). For instance, as reviewed by Druzhinina and Kubicek (2016), as well as others, almost all of the lignocellulolytic enzymes needed for the hydrolysis step can be produced by fermentation in *T. reesei*. However, the catalytic activity of some of the enzymes in the cellulase cocktail is still too low, and the composition of the secreted enzyme mixture may not be optimal due to some enzymes being present in limiting amounts. To overcome this bottleneck at the enzymatic hydrolysis step of lignocellulose, a significant amount of work has been directed towards understanding and improving the strain by improving the performance of the respective enzymes. These investigations have resulted in industry using *T. reesei* almost exclusively for cellulase production, despite the fact that other fungi also produce powerful cellulolytic mixtures (Druzhinina and Kubicek, 2016; Grujić *et al.*, 2019).

The genomic sequencing of many *Trichoderma* spp. has revealed that the number of secondary metabolite biosynthetic gene clusters (most of which are silent under laboratory conditions) far exceeds that of the identified compounds, suggesting great potential from a genetic perspective for drug or agent mining in these fungi (Kubicek *et al.*, 2019). Using genetic modification methods, many of the *Trichoderma* genes involved in interactions with other fungi have also been functionally characterized, and their activity can be further investigated for enhanced mycoparasitic abilities (Chenthamara and Druzhinina, 2016; Druzhinina *et al.*, 2011). Researches on these aspects in other filamentous fungi such as the genera *Aspergillus* and *Penicillium* (Eurotiales, Ascomycota) can be found in several reviews (Brakhage, 2013; Keller, 2019; Macheleidt *et al.*, 2016).

Improving the industrially or agriculturally relevant properties of *Trichoderma* spp. is closely related to the development of methods for genetic manipulation in these fungi. In this chapter, we will summarize and briefly describe the methods that have been developed for genetic modification of *Trichoderma* strains and illustrate some examples using these methods. We will then summarize some applications of the promising new technologies such as the CRISPR/Cas9 system, the currently most powerful gene-editing tool available, for further progress.

Untargeted Genetic Recombination by Classical Mutagenesis

The classical methods of mutagenesis, including forced random mutagenesis, sexual crossing, protoplast fusion, and parasexuality, have been developed to introduce mutations without previous knowledge of the gene or genome structure. These methods are applicable only when the desired genetic alteration has a readily identifiable phenotype.

Forced Random Mutagenesis Resulted in the Creation of the Industrial Hypercellulolytic Strains of *T. reesei*

The current most commonly used hypercellulolytic strain, *T. reesei* RUT C30, was obtained by multiple rounds of random mutagenesis of the parental wild-type strain QM 6a isolated from the Solomon Islands (see Peterson and Nevalainen, 2012 for the review), which massively increased its cellulase yields. The first attempt to obtain a high cellulase-producing strain by mutagenesis was conducted by Mandels *et al.* (1971), who introduced an irradiation method to mutate the wild-type *T. reesei* QM 6a strain. Conidia from QM 6a were suspended in distilled water and irradiated at 20°C with high energy electrons from a 24-million electron volt, 18-kw linear accelerator (Fig. 1). After applying the 0.05 megarad dose, a strain designated as QM 9123 was isolated

Fig. 1 The principles of three classical mutagenesis methods (A) and the *Trichoderma reesei* mutants derived via these methods (B). WT, wild-type *T. reesei* QM 6a; UV, ultraviolet; LA, linear accelerator; NTG, N-nitroguanidine.

because it produced twice as much cellulase as the parental strain. A second mutagenesis was performed using high-voltage electrons that led to the strain QM 9414. Compared to the wild type, this strain had a 2–4 fold increase in extracellular cellulase and protein production, but it was catabolite repressed (Montenecourt and Eveleigh, 1977b).

Another mutagenesis was performed on QM 6a via a three-step mutagenesis procedure that involved both ultraviolet (UV) irradiation and chemical mutagenesis. For the first step, QM 6a spores were exposed to UV irradiation under conditions to produce a 0.1% survival rate and plated on a catabolite-repression screening medium, which led to the isolation of strain M7. Chemical mutagenesis of this strain was then performed using N-nitroguanidine, leading to the partially carbon catabolite-derepressed strain NG14. This strain produced more extracellular protein with filter-paper activity than QM 9414 and had 2–5 times higher β -glucosidase activity. Another round of UV mutagenesis (as described above) was performed, which finally led to the hyper-cellulolytic (similar production and activity levels as NG14 in shaking flasks) and catabolite-derepressed strain RUT C30 (Montenecourt and Eveleigh, 1977a,b, 1979). This strain is still one of the strongest cellulase-producing *T. reesei* strains available in the public domain. A genome-wide analysis revealed that the strain is missing an 85 kb genomic fragment that contains 29 genes, including primary metabolism enzymes, transport proteins, and transcription factors. Interestingly, this loss was already present in the strain NG14 (Fig. 1) and is not associated with catabolite-repression genes such as the *cre1* locus (Seidl et al., 2008). However, the mutation of the *cre1* locus was shown to be specific to RUT C30.

In the last decade, to eliminate the glucose repression related to cellulase and hemicellulase gene expression, Ike et al. (2010) screened two *T. cf. reesei* ATCC 66589¹ (The accurate and precise molecular identification of this strain to the species level is not possible (Cai and Druzhinina, 2020). Based on the ITS1 and 2 (NCBI accession KU729058) and 28 S (NCBI accession KU729141) rRNA DNA barcode sequences, the strain can be attributed to a group of closely related species that includes *T. reesei*, *T. parareesei*, *T. gracile*, and *T. beinartii* (as for October 2020) (see “Relevant Website section”); the same hereafter) mutants that were able to produce cellulases when grown on a glucose-containing basal medium (Kawamori et al., 1986). Sreenivasulu et al. (2014) improved the antagonism and carbendazim tolerance of the *T. reesei* strains TCT4 and TCT10 through ethyl methane sulfonate (EMS)-mediated mutagenesis.

Random mutagenesis has also been applied in other *Trichoderma* species. Abbasi et al. (2016) enhanced the antagonistic ability of *T. cf. harzianum* 65¹ against several plant-pathogenic fungi by mutating the wild type with a Gammacell irradiator at a dose of

250 Gray $\cdot$ s⁻¹. Wang *et al.* (2020a) further modified the mutant *T. cf. harzianum* EU2-77 (a mutant derived from *T. cf. harzianum* NP13a¹) by UV irradiation, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, and EMS treatments, leading to a mutant (EUA20) with enhanced cellulase and reduced sugar production.

A schematic diagram of the random mutagenesis process using UV, irradiation and chemical mutagens is shown in Fig. 1. The best mutagens are those that can induce high mutation rates with little lethality. However, searching for the desired strains is laborious, unless a means of selecting the desired mutants is available. Choosing suitable mutagens and optimizing doses for the target strains can increase the mutagenesis efficiency.

In Vitro Sexual Crossing, the Dedicated Gift for *T. reesei*

Sexual reproduction is essential for the long-term population persistence of most eukaryotes, though sometimes asexual reproduction is a more efficient mechanism for dispersal. Sexual crossing, the crossing of the genetic information from two different parents, can make some progeny possess unique beneficial characteristics. However, this method can only be used to improve the strains of species with a sexual cycle (Seidl and Seiboth, 2010) completed *in vitro*. For a long time, this method was not available for any *Trichoderma* species. In 1996, Kuhls *et al.* (1996) found that the cellulase producing *T. reesei* was an asexual clonal line derived from a population of the tropical and sexually reproducing *T. reesei* (at that time named for its teleomorph *Hypocrea jecorina*, a name now abandoned). However, attempts to cross *T. reesei* QM 6a with sexually compatible strains isolated from the teleomorph repeatedly failed. Researches with the QM 6a strain discovered that it had a MAT1-2 mating-type locus, while a MAT1-1 mating-type locus was found in an isolate called CBS 999.97, suggesting these strains belong to a heterothallic species (Martinez *et al.*, 2008). The strain CBS 999.97 can be crossed with QM 6a and its mutants (Tisch *et al.*, 2017), but further analysis has shown that QM 6a and its derived strains can only act as the male mating partner. When the MAT1-2 locus in the QM 6a was replaced with the MAT1-1 locus, no fruiting bodies were observed during crosses between the transgenic strain and QM 6a, suggesting QM 6a was female sterile. However, after the mating-type locus was artificially inverted in the MAT1-1 isolates, the strains could be sexually crossed. A genomic analysis by Linke *et al.* (2015) revealed that two genes, encoding an unknown C2H2/ankyrin protein and the WD-protein HAM5, were essential for fruiting body formation when QM 6a was crossed with CBS 999.97. Importantly, the sexual cycle provides an invaluable tool for classical genetic analyzes and forms a basis that greatly facilitates genetic work and industrial strain improvement with this fungus. Unfortunately, thus far this is only possible with *T. reesei*, as no other *Trichoderma* species have been found that could mate under laboratory conditions (Seidl *et al.*, 2009; Chenthamara *et al.*, 2021).

Protoplast Fusion and Parasexuality, the Cloud of *Trichoderma* Strain Improvement

Fungal protoplasts, cells not protected by a cell wall, are formed by artificially removing the cell wall with lysing enzymes, and protoplast fusion is a recombination technique used to transfer cytosolic organelles from one protoplast to another (Muralidhar and Panda, 2000). The process generally consists of three steps: cell wall breakdown, protoplast fusion, and protoplast regeneration. The fungal cell wall is made up of chitin, glucans, mannans, and glycoproteins (Bowman and Free, 2006), and its breakdown requires activity of the relevant enzymes. Protoplast regeneration is then required to obtain viable progeny. The vital part of this process is protoplast fusion, which can be mediated by different agents such as a virus (Okada, 1988), a chemical or electric shock (Wang *et al.*, 2008). Protoplast fusion can be an appropriate tool for improving some fungal strains (Dillon *et al.*, 2008). To obtain fusants with desirable characteristics, the ideal approach should include intra-species, inter-species, and inter-genera fusions.

The first *Trichoderma* protoplast fusion was performed by Toyama *et al.* (1984) using immature conidia of the *T. reesei* mutant QM 9414 (they later also used the “smaller nuclei”; Toyama and Toyama, 1995). In that process, protoplasts derived from the two strains were mixed at an equal ratio, polyethylene glycol (PEG) 6000 and CaCl₂ were added to mediate the protoplast fusion process, and the protoplast suspension was plated on a regeneration medium to yield the fusion products. The conidia generated on the fusant colonies showed diverse phenotypes: DNA content was 1.2–2.0 times higher than that of the parents, colonies developed from a single conidia had a higher mycelia density, and their traits were stably inherited. In another experiment, Ogawa *et al.* (1987) used differentially pigmented mutants to conduct the protoplast fusion. The conidia (white and brown) of two mutants originating from *T. reesei* QM 9414 (green conidia) were used to generate the protoplasts, which were then treated with ethylene glycol and effectively fused. The heterokaryons had improved cellulase, xylanase, and β -glucosidase activities compared to the parental strain (QM 9414). Additionally, the use of pigmented mutants may also avoid a dependence on auxotrophic mutants, which can have decreased protein production compared to the parental strain.

Parasexual recombination, discovered by Pontecorvo and Roper (1952) in *Aspergillus nidulans*, is recombination outside of the sexual cycle in which neither meiosis nor fertilization occurs. Although the steps of the parasexual cycle are fundamentally different from those in the sexual cycle, they ultimately result in new genotypes. Classical genetic analyzes of asexual species depend on the parasexual cycle (Clutterbuck, 1996). Parasexual recombination related to reproduction can result in the recombination of genes from different individuals, but it does not involve the formation of a zygote by fertilization as in sexual reproduction. Parasexual crosses between strains with different beneficial mutations for the production of industrially valuable materials can result in the isolation of haploid progeny with the beneficial mutations from both parents combined through

chromosome reassortment (Bawa and Sandhu, 1994; Bodie *et al.*, 1994). Techniques for heterokaryosis and diploid formation have also been used to obtain higher yields of industrial metabolic products in many fungal strains. In addition, the use of markers such as different conidia colors allows one to follow the haploidization, diploid heterozygosis, and heterokaryosis processes during the cycle (Pontecorvo, 1956).

As previously mentioned, in *T. reesei* QM 9414, the heterokaryons from two differently colored mutants generated green conidia, suggesting that a parasexual cycle existed in the strain (Ogawa *et al.*, 1987). However, some steps of the parasexual process were putatively missing in *T. pseudokoningii*. Stable haploid and unstable hyperhaploid recombinants were recovered from heterokaryons without the isolation of a diploid (Bagagli *et al.*, 1995). The progeny strains from inter-strain crosses of *T. harzianum*, *T. hamatum*, *T. koningii*, and *T. viride* showed isozyme phenotypes identical to either one or the other of the parental strains, suggesting they did not originate from a parasexual mechanism, but rather that the nuclear form from one of the parents had degraded (Barcellos *et al.*, 2011; Sivan *et al.*, 1990; Stasz and Harman, 1990). Therefore, the parasexual cycle does not work in all the *Trichoderma* species thus far tested. Nevertheless, parasexual recombination has the potential to produce superior fungal strains for medical, industrial, and agricultural uses by recombining entire genomes to get numerous potentially useful properties in a single experiment, which may be better accepted by the public than are products derived via transgenesis (Strom and Bushley, 2016).

Targeted Genetic Recombination

Recombination Based on Selective Markers

Improving a strain by recombination with selective markers requires a potent transformation system that must meet at least three requirements: (1) unaltered phenotypes in mutants compared to the wild type; (2) a high rate of homologous recombination (gene replacement) events; (3) and the possibility for bidirectional positive selection (Gruber *et al.*, 2012; Steiger *et al.*, 2011). A selectable marker is a gene introduced into the genome that confers a trait suitable for artificial selection. Over the last three decades, more than ten species within the genus *Trichoderma* have been genetically investigated due to their industrial and/or agricultural application potential. Thus, efficient marker systems have been developed that can be divided into two main groups, the drug resistance genes and the auxotroph genes (Table 1).

For now, most *Trichoderma* mutants genetically engineered via recombination are produced based on the acquisition of resistance to certain xenobiotic compounds (Table 1) via introduction of the respective resistance genes into the strains. These marker genes give the recipient strains the ability to resist the antibiotic compounds. Thus far, most resistance marker genes are derived from bacteria. To be successfully expressed in fungi, the genes need to be placed into a cassette constructed with appropriate fungal promoters and terminators. The recipient cells are then plated on selective medium containing the antibiotic, and only the transformants harboring the marker cassette survive, and are thus identified.

Hygromycin B is an aminoglycoside antibiotic that inhibits protein synthesis in prokaryotes and eukaryotes by interfering with translocation and causing misreading (González *et al.*, 1978; Mach *et al.*, 1994). The *hph* gene from *Escherichia coli*, encoding a phosphotransferase that inactivates hygromycin B (Gritz and Davies, 1983), is the selectable marker gene used predominantly in *Trichoderma* spp. (Table 1). In 2012, (Gruber *et al.*, 2012) established the neomycin phosphotransferase II-encoding gene (*nptII* from *E. coli*, also termed *neo*) as a novel selectable marker for transformation into *T. atroviride* to confer geneticin (G418) resistance. This *nptII* marker cassette has since been efficiently transferred into other species such as *T. hypoxylon*, *T. reesei*, *T. sp. aff. guizhouense*, and *T. harzianum* (Liu *et al.*, 2018; Wu *et al.*, 2019; Chenthamara *et al.*, 2021). The bleomycin resistance gene (*ble*) from *Streptoalloteichus hindustanus* (Actinomycetales, Actinobacteria) has also been adapted for transformation into four *Trichoderma* spp., with phleomycin (bleomycin) used as the selection agent. The phosphinothricin resistance gene *bar* from *Streptomyces viridochromogenes* (Actinomycetales, Actinobacteria) has also been introduced into *T. reesei* for use as a selectable marker.

The drawbacks of using antibiotics, including fungicides, for selection is that they are expensive and can interfere with the regular function of the targeted gene (Calcáneo-Hernández *et al.*, 2020). An alternative to avoid the use of antibiotics is to generate auxotrophic transformation systems for genetic use. Auxotrophic selectable markers rely on the nutritional background of the recipient strains. The auxotrophic strains have either a mutation or a genetic form of a gene that makes them deficient in synthesizing an essential nutritional compound. By complementing the strains with a functional copy of the corresponding gene, the auxotrophic strains become prototrophic, obtaining the ability to synthesize the specific compound. For example, the *argB* gene from *Aspergillus nidulans* encodes ornithine transcarbamylase, which synthesizes arginine (Penttilä *et al.*, 1987). In the *T. reesei* autotrophs derived from UV-mutagenized conidia, this gene is functionally impaired, and thus they cannot grow without exogenous arginine. If a transformation in these strains is successful, the recipients obtain the ability to synthesize arginine and can grow without a direct arginine supply. Similarly, a selectable marker system employing D-mannitol as a selective carbon source and osmotic stabilizer has been developed based on the *hxx1* gene (encoding hexokinase) in the hexokinase-negative *T. reesei* strain TU-6H. Successful transformation with the *hxx1* gene allows the transformants to grow on D-mannitol as the sole carbon source (Zhang *et al.*, 2010).

For now, the most commonly used auxotrophic marker gene in *Trichoderma* spp. is *ura3*, encoding orotidine-5'-phosphate decarboxylase, the yeast *pyr4* homolog. The gene *ura5*, which encodes orotate phosphoribosyl transferase, can also be used as an auxotrophic marker, but it is less efficient compared to *ura3* (Bergès and Barreau, 1991; Steiger *et al.*, 2011). In this selection system, the pyrimidine analog 5-fluoro-orotic acid (5-FOA) is generally used for the positive selection of uracil (uridine)

Table 1 Selectable markers used for *Trichoderma* transformations

Marker origination	Encoding gene	Marker gene function	Phenotype of transformants	Reported species	References
Drug resistance	<i>hph</i>	Encoding hygromycin phosphotransferase	Hygromycin B resistance	<i>Trichoderma reesei</i>	(Mach <i>et al.</i> , 1994)

^aIdentified as *T. harzianum* (IMI 206040) in the original publication of Herrera-Estrella *et al.*, 1990.

^bFrequently used with 5-fluoroorotic acid (5-FOA) for bidirectional positive-selection system and also frequently used with *Cre/loxP* recombination system for reusable marker use.

auxotrophic mutants. 5-FOA is catalyzed by URA5 and URA3 to obtain 5-fluorouridine 5'-monophosphate and 5-fluorouracil (Boeke *et al.*, 1984). The latter product inhibits thymidylate synthase activity, which consequently results in thymine nucleotide depletion, affecting DNA synthesis (Boeke *et al.*, 1984; Calcáneo-Hernández *et al.*, 2020; Gruber *et al.*, 1990). Therefore, the toxicity of 5-FOA on those wild-type or complemented strains facilitates their selection, whereas mutants deficient in *ura3* or *ura5*, essential for uracil synthesis, can grow on 5-FOA-containing medium supplemented with uridine/uracil (Bergès and Barreau, 1991; Gruber *et al.*, 1990; Hartl and Seiboth, 2005; Steiger *et al.*, 2011). Another example is amidases, which are hydrolytic enzymes that catalyze the conversion of carboxylic amides to the corresponding carboxylic acid and ammonia. As amidases are present in only a few fungal species (Penttilä *et al.*, 1987), the *A. nidulans amdS* gene can be used as a selectable marker for successfully transforming *Trichoderma* spp. The transformants carrying the *amdS* gene can easily be selected using acetamide as the sole carbon or nitrogen source (Penttilä *et al.*, 1987; Suominen *et al.*, 1993).

However, the most commonly found *Trichoderma* species, such as *T. harzianum*, *T. guizhouense*, *T. virens*, *T. atroviride*, *T. asperellum*, *T. brevicompactum*, and *T. hamatum*, are prototrophic or sensitive to only one or two of the antibiotics mentioned, making it difficult to perform multiple gene transformations. One proposed strategy is to use the *Cre/loxP* recombination

Fig. 2 Schematic diagram of CRISPR/Cas9-mediated gene manipulation. The Cas9 protein can be expressed *in vivo* in the host cell or added *in vitro*. The gRNA can either be synthesized *in vitro* or produced *in vivo* with an AMA-based autonomously replicating plasmid. Strains listed under each method are those that have already been established with the CRISPR/Cas9 system using that method.

system (also see below) adapted from bacteriophage P1 (Sternberg *et al.*, 1981), which involves the excision of DNA fragments (usually the marker gene cassette) flanked by *loxP* sites that catalyzed by the expression of CRE recombinase (Steiger *et al.*, 2011). In this circumstance, *Cre/loxP* offers the possibility of serially targeted gene deletions with absolute marker recycling in the fungus.

Recombination Based on Markerless Systems

Marker genes can be removed once a transformation has succeeded, and two methods have been reported for removing them by recombination (Bischof and Seiboth, 2014). The first method is homologous recombination-mediated excision. In previous research with *T. reesei* QM 6a, the auxotrophic *ura3* gene (termed *pyr4* in the original publication) was used as a selective marker gene (Hartl and Seiboth, 2005). The plasmid was constructed by inserting the *ura3* gene between two direct repeats of the *Sh ble* (zeocin resistance) gene. The up- and downstream regions of the targeting genes were then cloned into the plasmid to complete the final vector. After transformation, the targeted gene was deleted, and the *ura3* gene was inserted. Selection medium without 5-FOA and uridine (uracil) was used to screen for the positive transformants. After positive selection, the transformed mutants were plated on medium containing 5-FOA, and the *ura3* marker gene was excised via recombination among the direct repeats of the *Sh ble* fragments.

The other method for markerless recombination is the *Cre/loxP* system as briefly mentioned above, a site-specific recombination system mediated by heterologous site-specific recombinases (Fig. 2) that requires the introduction of a site-specific recombinase (CRE recombinase) by transformation. This method permits the unlimited reuse of the same marker and has been applied in *T. reesei* QM 6a (Steiger *et al.*, 2011). First, the human *LIG4* (DNA ligase 4, which joins single-strand breaks in a double-stranded polydeoxynucleotide and is essential for DNA double-strand break repair via non-homologous end joining) homologous gene *tmus53* was deleted in QM 6a to create a non-homologous end joining-deficient strain, which can lead to significantly higher homologous recombination efficiency (Ninomiya *et al.*, 2004). For this purpose, a deletion cassette containing the phosphinothricin resistance (*bar*) marker was constructed and transformed to obtain a *tmus53* deficient strain (QM6aΔ*tmus53*). Another cassette containing two *loxP* sites flanking the *hph* and *amdS* cassettes (*loxP*-*amdS*-*hph*-*loxP*) was then used to replace the *bar* gene. At the same time, the *pyr4* gene was replaced by the *cre* gene (encoding CRE recombinase) under the control of the *xyn1* (encodes xylanase I) promoter. This step yielded the strain QM6aΔ*tmus53*Δ*pyr4*, which was resistant to hygromycin B and could utilize acetamide as a nitrogen source. The QM6aΔ*tmus53*Δ*pyr4* strain was then cultivated on xylan, resulting in excision of the marker genes *hph* and *amdS* by the *Cre/loxP* system, meaning these two marker genes can be reused repeatedly to delete any genes of interest. When the aim of the gene deletions was achieved, the *cre* gene was replaced by the *ura3* gene to obtain the marker free strain QM6aΔ*tmus53*. Nevertheless, this method always retains one *loxP* site in the genome after each deletion.

Methods for Introducing Recombinant DNA Into *Trichoderma*

Agrobacterium tumefaciens-mediated transformation

Agrobacterium tumefaciens (syn. *Rhizobium radiobacter*, Rhizobiales, Proteobacteria) is a pathogenic Gram-negative alpha-proteobacterium that infects plants or fungi by inserting DNA into the nucleus of the host cell via a plasmid (the Ti-plasmid). In plants, it forces the abnormal growth of tissues (galls) that are used by the bacterium (Barton *et al.*, 2018; Gelvin, 2003). The Ti plasmid contains a virulence region with the *vir* genes that encode the virulence proteins involved in the formation, transport, and integration of the T-DNA. The concept of the *A. tumefaciens*-mediated transformation (AMT) method is based on the fact that all the T-DNA sequences can be replaced by other DNA sequences. Thus, an altered T-plasmid offers the opportunity for a DNA fragment to be placed between two 25 bp direct repeats (the left and right borders required to transfer the T-DNA) and thus be transformed into the host cell (Gelvin, 2003). Although frequently called “transformation”, this process is more correctly described as “trans-conjugation” (Cai *et al.*, 2020b). The T-DNA transfer of *A. tumefaciens* requires inducers such as phenolic compounds, which are often used. After being induced by acetosyringone, the virulence genes begin to express, and the virulence proteins help generate single-stranded DNA copies of the T-DNA, which are then transferred into the recipient (Michielse *et al.*, 2005). If the T-DNA carries a homolog, homologous recombination will occur. Otherwise, it will integrate ectopically when the T-DNA does not homologously recombine. Many factors influence AMT efficiency in fungi, including the fungal starting materials (protoplasts, spores, mycelium, or fruiting body tissue), concentration of the inducer, and co-cultivation conditions (ratio between the *A. tumefaciens* and recipient, length of the co-cultivation period, temperature, and pH), making AMT a complicated procedure for fungal transformations.

T. reesei was the first species to be tested to check whether AMT can work for the fungus (de Groot *et al.*, 1998). The conidia of *T. reesei* were co-cultured with others from *A. tumefaciens*. T-DNA carrying the selectable marker gene was transformed into *T. reesei*, and the resulting conidia were then plated on selective medium to screen for positive transformants. The stability of the marker resistance was confirmed by repeatedly replating the transformants on fresh selective medium. Zhong *et al.* (2007) successfully applied the AMT method in *T. reesei* QM 9414 and established a procedure with a higher efficiency AMT. However, a characterization of the T-DNA insertion junctions suggested that T-DNA integration occurred at random positions in the *T. reesei* genome by a process of non-homologous recombination.

Another modified AMT method that can generate gene-deleting strains efficiently by homologous recombination was established and applied in *T. atroviride* P1 to delete two genes (Zeilinger, 2004). The respective gene deletion cassettes were constructed in a plasmid (pAN7-1) containing the *E. coli hph* gene cassette (see above). The whole disruption construct, flanked by the 5' and 3' non-coding sequences of the *tmk1* and *tga3* genes (the targeting genes), was inserted between the left and right border repeats of the binary vector pTAS5. The transformation was implemented by plating the co-cultivations onto sterile nitrocellulose membranes placed on an induction medium. After transformation and selection, the positive transformants showed highly efficient *tmk1* and *tga3* deletion. The AMT method has also been adopted for transforming different strains of *T. britannicum* (shown as *T. harzianum* in the publication of Cardoza *et al.*, 2006), *T. cf. aff. guizhouense* (Zhang *et al.*, 2016), *T. longibrachiatum* (Cardoza *et al.*, 2006), *T. asperellum* (Cardoza *et al.*, 2006), *T. brevicompactum* (Tijerino *et al.*, 2011), and *T. arundinaceum* (Lindo *et al.*, 2018). A detailed AMT procedure can be found in Cai *et al.* (2020b).

PEG-mediated protoplast transformation

Protoplast transformation is the most widely used method for introducing DNA into a fungal cell. The first successful attempt was based on a PEG/CaCl₂-mediated protoplast transformation in *T. reesei*. The *argB* gene from *A. nidulans* was used as an auxotrophic marker together with a corresponding *argB*-deficient mutant (Penttilä *et al.*, 1987). Protoplast transformations require the preparation of protoplasts from fungal cells using various cell-wall degrading enzymes. The starting cells can be germinating conidial spores or young mycelial fragments. The enzymes used to degrade the cell walls in *T. reesei* are usually from *T. harzianum*, while for other fungi, the lysis enzymes generally are from snail stomach and the bacterium *Arthrobacter luteus* (Actinomycetales, Actinobacteria). After hydrolyzation, the protoplasts are stabilized with sodium chloride, magnesium sulfate, mannitol, or most commonly, D-sorbitol or sucrose. They can then be frozen at −80°C for later use (see Bischof and Seiboth, 2014 for a review).

DNA uptake is mediated by the presence of calcium ions (Ca²⁺) and a high PEG concentration. The calcium ions promote the salt precipitation of DNA on the protoplast surface, and PEG serves as a glue to keep the protoplasts in close contact with the DNA molecules, thereby facilitating DNA uptake. The protoplasts are then regenerated on selective media, where only the transformed cells can grow (Ruiz-Díez, 2002). In contrast to AMT, protoplast transformation often leads to a high copy number of DNA insertions. Recently, a well-established PEG-mediated protoplast transformation procedure has been adopted in species from the *Harzianum* clade (e.g., *T. harzianum* and *T. cf. aff. guizhouense*) that favors an outcome with genetically modified mutants for several different genes (Cai *et al.*, 2020a,b; Gao *et al.*, 2020; Meng *et al.*, 2020; Pang *et al.*, 2020; Zhang *et al.*, 2019). This procedure has been summarized by Cai *et al.* (2020b).

RNA Interference

RNA interference (RNAi) is a biological process in which gene expression is inhibited by targeting the specific mRNA (Bischof and Seiboth, 2014). The method is mediated by double-stranded RNA (dsRNA), and successful implementation requires two

components: RNA-induced silencing complex (RISC) and the enzyme Dicer. First, dsRNA with homology to the gene of interest is expressed in the fungal host strain, which is then cleaved into short interfering RNA (siRNA). The double-stranded siRNA is then unwound into two individual strands. One of the single-stranded RNAs, called the passenger strand, is degraded. The other, called the guide strand, is incorporated into RISC, pairs with its complementary mRNA, and induces cleavage, which results in the gene being silenced (Meyer, 2008).

RNAi was applied in *T. reesei* RUT C30 to silence the expression of the cellobiohydrolase II-encoding gene *cel6a* (Brody and Maiyuran, 2009), which was used as the DNA template to construct the silencing vector pMai148. The successful transformants had lower *cel6* expression levels, and an RT-qPCR evaluation showed that the level of *cel6a*-specific mRNA in the transformants was lower than that in wild type. Another improved RNAi system for *Trichoderma* was developed by He *et al.* (2015). This system has dual promoters for efficient RNA silencing in *T. reesei*. The *rp2* (encodes ribosomal protein P2; He *et al.*, 2013) promoter from *T. reesei* and the *trpC* (encodes a polypeptide involved in tryptophan biosynthesis; Hamer and Timberlake, 1987) promoter from *A. nidulans* were used to construct the pCAMBIA1300–1-dual plasmid. To construct a vector for gene silencing, the target gene is directly inserted into a specific site in pCAMBIA1300–1-dual. This modified system can also be used to co-silence more than one gene. Unfortunately, this RNAi system is uncontrollable in *T. reesei* or only works on certain substrates. Wang *et al.* (2018) developed a copper-controlled RNAi system in which the copper-responsive *tcu1* promoter was introduced into *T. reesei* QM 9414. This system was used to control the expression of *xyl1*, which encodes the transcriptional activator of the cellulase and hemi-cellulase genes (Stricker *et al.*, 2006), and *cel7*, including the exoglucanase-encoding gene *cel7a* and the endoglucanase-encoding gene *cel7b* (Kajisa *et al.*, 2009). The transcriptional levels of these two genes were both reduced when copper was absent in the medium, whereas they were restored when copper was added.

Promoter Engineering Approaches

Manipulating the promoter of genes is also an effective strategy to regulate their expression. Promoters are the regulatory regions upstream of the transcriptional start site, and they control gene transcription. Promoters also provide information and factors to RNA polymerase. In general, the promoters used for strain engineering can be classified into two types: constitutive promoters and tunable promoters.

Constitutive promoters are expressed independently and are not affected by environmentally induced factors. They regulate the expression of basal genes, assumed to be produced at a constant rate, and thus their activity is not flexible. Numerous constitutive promoters have been used such as *cdna1* (encodes a hypothetical protein with a high transcriptional level; Nakari-Setälä and Penttilä, 1995), *tef1* (encodes translation elongation factor 1 alpha; Nakari-Setälä and Penttilä, 1995), *eno1* (encodes enolase; Li *et al.*, 2012), *gpd1* (encodes glyceraldehyde-3-phosphate dehydrogenase; Li *et al.*, 2012), *pdcl* (encodes pyruvate decarboxylase; Li *et al.*, 2012), *phi1* (encodes pyruvate kinase; Kurzatkowski *et al.*, 1996), and *rp2* (see above). The *cdna1* and *tef1* promoters were isolated by screening cDNA libraries for genes highly expressed during growth on D-glucose-containing media, and they have been used for overexpressing different genes under these culture conditions (Nakari *et al.*, 1993). In *T. reesei* QM 9414, the *cbh1* (encodes cellobiohydrolase I) promoter is repressed by glucose (Penttilä *et al.*, 1993). Nakari-Setälä and Penttilä (1995) used the *cdna1* and *tef1* promoters to manipulate QM 9414, making the fungus secrete active cellobiohydrolase I and the endoglucanase I catalytic core when cultivated on medium containing glucose. The results showed that the *cdna1* promoter provided the highest yield, accounting for more than half of the total protein secreted by the mutant; the production levels obtained with the *tef1* promoter were much lower. The promoters for *eno1* and *pdcl* are also well-adapted for cultivation on D-glucose, as shown when their activities were compared by expressing xylanase in *T. reesei*. The recombinant strains obtained by Li *et al.* (2012) were cultivated in glucose-containing medium, which led to an extremely high yield of recombinant xylanase II (XYN II). Linger *et al.* (2015) utilized the *eno1* promoter to control the expression of the *cel7a* gene in a Δ *cel7a* strain, and the purified CEL7A produced from the mutant grown on glucose showed remarkably consistent activity. In contrast, purified CEL7A from the same strain grown on lactose demonstrated significantly higher variability in its activity.

Tunable promoters are inducible or repressible depending on the presence or absence of activating or repressing factors. An inducible promoter should have no basal expression, but have considerably enhanced expression on the addition of the inducer. Conversely, the expression of a repressible promoter should be significantly lowered by the addition of a repressing substance. For the mutant *T. reesei* D7, which was generated from *T. reesei* RUT C30, Li *et al.* (2017) used the *cbh1* promoter induced by cellulose to regulate the expression of *cbh2*, whose expression is usually lower than that of *cbh1*. The transformant, named *T. reesei* TH18, had the highest yield when induced by pre-treated corn stove. For *T. reesei* PC-3–7, the gene encoding XYN III showed its highest expression levels among the xylanase genes in response to cellulosic carbon. The *xyn3* promoter has also been found to be suitable for expressing specific genes encoding highly functional proteins. Hirasawa *et al.* (2018) has constructed various chimeric *xyn3* promoters by utilizing the *xyn1* cis-acting region. This efficient chimeric *xyn3* promoter was then used to control the high-performance BGL from *Aspergillus aculeatus* (AaBGLI) in the *T. reesei* PC-3–7 strain. The transformed strains had improved BGL activity, which also indicates a high saccharification ability with induction by cellulose.

Given that the non-directional mutations and DNA combinations achieved through forced random mutagenesis, sexual crossing, protoplast fusion, and parasexuality require time- and labor-intensive processes, the application of such classical mutagenesis techniques have been falling into disuse since the second sequencing revolution. Neither the recombinant methods based on a limited number of selectable marker genes nor the markerless systems allow for efficient multiple-gene editing. Even so,

by applying the methods described above in *Trichoderma* biology and biotechnology, great progress has been achieved in our understanding and utilization of this fungus. Given that the *Trichoderma* spp. genomes are largely unexplored, and the genetic bases of domestication traits of interest are poorly understood, robust genetic tools are still highly desired.

CRISPR/Cas9, the Next-Generation Genome Editing Revolution and Its Application in *Trichoderma*

In recent years, the type II clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated protein (Cas) system has been applied for gene editing in various species of eukaryotes, including filamentous fungi. The CRISPR/Cas9 system is composed of a Cas9 nuclease and a single-guide RNA (sgRNA), which consists of a target-recognizing CRISPR RNA (crRNA) and an auxiliary noncoding trans-activating crRNA (tracrRNA) (Jinek *et al.*, 2012). The complex that the sgRNA binds to Cas9 catalyzes a double-strand break in the target DNA site (20 bp) that matches the sgRNA protospacer and a downstream protospacer adjacent motif (PAM) sequence (Mali *et al.*, 2013). The target sites must lie immediately at the 5' end of the PAM sequence and match the canonical form 5'-NGG (N represents any possible nucleotide). The Cas9 nuclease can be directed to any DNA sequence of the form N₂₀-NGG simply by altering the first 20 bp of the gRNA corresponding to the target DNA sequence (Sander and Joung, 2014).

One of the first attempts to establish the CRISPR/Cas9 system in filamentous fungi was performed with *T. reesei* by Liu *et al.* (2015). In that study, a codon-optimized Cas9 with the SV40 nuclear localization signal (NLS) was integrated into the genomes of *T. reesei* strains QM 6a and RUT C30. Since knowledge of a confirmed RNA polymerase III-based promoter in *T. reesei* was lacking at that time, the authors introduced an *in vitro* synthetic sgRNA to edit the targeting genes by protoplast transformation. They first designed the sgRNA to target the *ura5* gene, which can undergo selection on minimal medium containing 5-FOA. To test the incidence of homologous recombination with the CRISPR/Cas9 system, they chose the gene *lae1* (encodes a putative methyltransferase; Seiboth *et al.*, 2012) as a target and used the exogenous gene *pura5* (encodes URA5 from *Penicillium oxalicum*) as the selectable marker. In this case, the designed sgRNA and the *lae1* donor DNA (dDNA) segment (containing the 5' and 3' regions of *lae1* and the *pura5* cassette) were co-transformed. The results indicated that the *lae1* gene was replaced by the selectable marker cassette in all transformants. A pair of 200 bp homology arms was sufficient to obtain homologous integration in the mutants, with homologous recombination frequencies of $\geq 93\%$. In another experiment, the two genes *vib1* (encodes a putative link between glucose signaling and carbon catabolite repression; Xiong *et al.*, 2014) and *clr2* (encodes a transcription factor for cellulase gene expression; Coradetti *et al.*, 2012) were chosen as targets to test the efficiency of disrupting multiple genes. The efficiencies for achieving the simultaneous homologous recombination of two (16%–45%, depending on the molar ratio of sgRNA to dDNA) or three (4.2%) genes were relatively low.

Liu *et al.* (2015) did not detect the off-target effect of the CRISPR/Cas9 system. Four years later, however, Hao and Su (2019) found an unexpected off-target gene disruption in *T. reesei* QM 9414 that was caused by intracellularly expressed Cas9. Hence, they utilized the *in vitro* assembled ribonucleoprotein (RNP) Cas9/gRNA complex to disrupt the *cbh1* gene in *T. reesei* TU-6 (the uridine auxotrophic mutant of QM 9414), which was shown to be successfully disrupted, with large DNA inserts in the edited *cbh1* locus. This transient *in vitro* method may prevent the side effects caused by the *in vivo* expression of Cas9, which may be due either to the enzyme itself or the transgenic procedures. This experiment supports using this alternative gene editing tool for those filamentous fungi in which it is difficult to manipulate genes as well as for those fungi lacking codon-usage databases (because the *in vivo* Cas9 system requires codon optimization for use in eukaryotic cells). Interestingly, Rantasalo *et al.* (2019) adapted the RNP-based method for multiple-gene deletions, achieving a 12% simultaneous triple deletion efficiency for the *cbh2* (encodes cellobiohydrolase II), *egl1* (encodes endoglucanase I), and *egl2* (encodes endoglucanase II) genes. More recently, Zou *et al.* (2020) improved the transformation efficiencies of both homologous recombination and gene disruption without the use of any foreign DNA, but rather via chemical reagents. Adding the surfactant Triton X-100 increased the number of RNP transformations by enhancing RNP penetration. Furthermore, the addition of inositol or benomyl increased the formation of monokaryotic protoplasts, which also improved the efficiency of homozygous transformations.

As two new U6 promoters (RNA polymerase III-based promoters) were recently confirmed by Wu *et al.* (2020), the simultaneous *in vivo* expression of both Cas9 and sgRNA in *T. reesei* has also now been successfully achieved. Expressing sgRNA *in vivo* can save time in the experimental procedure and guarantees the sgRNA concentration, thus increasing the efficiency of the CRISPR/Cas9 system. Wang *et al.* (2020b) have also found that the native 5S rRNA promoter can be used to drive sgRNA expression in *T. reesei* (strain QP4), which was more efficient than using the heterologous promoter from *A. niger*. Fonseca *et al.* (2020) used this exogenous promoter to express an sgRNA *in vivo* to introduce six genetic modifications in *T. reesei* RUT C30, resulting in a remarkable increase in the protein secretion rates.

Acknowledgments

The authors wish to thank Christian P. Kubicek (Vienna, Austria) for comments to the manuscript draft. This work was supported by grants from the Ministry of Science & Technology of Jiangsu Province (BK20180533), National Natural Science Foundation of China (31801939) and China Postdoctoral Science Foundation (198162), all to FC. The work in Vienna (Austria) was supported by the Austrian Science Fund (FWF) P25613-B20, to ISD and the Vienna Science and Technology Fund (WWTF), LS13-048, to ISD.

Expression of Recombinant Fungal Proteins in *Pichia Pastoris*

Naoki Sunagawa, The University of Tokyo, Tokyo, Japan

Kiyohiko Igarashi, The University of Tokyo, Tokyo, Japan and VTT Technical Research Centre of Finland, Espoo, Finland

© 2021 Elsevier Inc. All rights reserved.

In studies of protein functions, the wild-type target protein can be used (Ayers *et al.*, 1978; Fägerstam and Pettersson, 1980), but endogenous expression levels are often low, and purification can be troublesome. Therefore, it is often more convenient to express recombinant proteins heterologously in another host. Various organisms, including bacteria, yeasts, insect cells, and animal cells, can be used as hosts. Each of them has characteristic advantages and disadvantages, and it is important to select an appropriate host for a particular purpose. In our research group, we often need at least several tens of milligrams of pure recombinant enzymes to study biomass-degrading systems derived from wood-decaying fungi. To obtain this level of recombinant protein production, we use *Pichia pastoris* as an expression host.

Introduction

In laboratory-scale production of recombinant and mutated proteins, *Escherichia coli* expression systems are most widely used (Rosano and Ceccarelli, 2014), and suitable vector systems are commercially available. However, protein synthesis in *E. coli* is intracellular, and the production amount of target protein per culture volume is limited. Moreover, since *E. coli* is a prokaryote, it is not suitable for the production of proteins derived from eukaryotes such as fungi, plantae and animalia.

We have used the yeast *P. pastoris* for more than 20 years as a host for production of recombinant fungal proteins and enzymes, as listed in Table 1. Most of the produced proteins are extracellular enzymes related to plant cell-wall metabolism, but we have also succeeded in synthesizing a membrane protein (anion exchanger) using this system (Tokuda *et al.*, 2011). Fewer host species and vector systems are available for *P. pastoris* compared to *E. coli* (Lin-Cereghino and Lin-Cereghino, 2007), but the yeast has the advantage that it can produce large amounts of the target protein due to the feasibility of high-density cultivation and the extracellular secretion of target proteins. Furthermore, *P. pastoris* secretes only low levels of endogenous proteins in culture (Cregg, 2007a), so purification of recombinant protein produced by *P. pastoris* is relatively easy. Levels of several grams per culture liter of recombinant fungal Carbohydrate-Active enZymes (CAZymes) have been obtained, and levels of several milligrams per culture liter are routinely obtained (Igarashi *et al.*, 2012; Mellitzer *et al.*, 2012; Nakamura *et al.*, 2013; Lombard *et al.*, 2014). High productivity of recombinant proteins is especially advantageous for studies such as enzymatic saccharification of biomass and preparation of crystals for neutron-beam structural analysis (Nakamura *et al.*, 2015). Moreover, since *P. pastoris* is an eukaryote, it can produce enzymes with post-translational modifications, such as glycan chain modification, or enzymes containing cofactors, such as flavin and heme (Yoshida *et al.*, 2001). Furthermore, *P. pastoris* is applicable to proteins that are generally difficult to express in recombinant form, such as G protein-coupled receptor (GPCR) and antibodies (Tokuda *et al.*, 2011; Shiroishi *et al.*, 2011; Ning *et al.*, 2003). Thus, *P. pastoris* has clear advantages over *E. coli* for producing eukaryotic proteins. Fig. 1 shows a working scheme for recombinant protein production using *P. pastoris*. In this chapter, we will describe these procedures and focus on some key points for success.

Construction of Expression Strains

A variety of *P. pastoris* host strains and vectors for recombinant protein expression can be purchased through Invitrogen, bioGRAMMATICS and ATUM (Ahmad *et al.*, 2014). This section describes points to consider when using these resources to construct a recombinant protein expression system.

Vectors and Type of Induction System

The expression of recombinant protein in *P. pastoris* can be controlled by several promoter systems (Vogl and Glieder, 2013). Among them, the alcohol oxidase (AOX) gene promoter in pPIC vector and the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene promoter in pGAP vector are commonly used for recombinant protein production in *P. pastoris*. The AOX promoter strongly induces the expression of recombinant proteins in the presence of methanol (Cregg *et al.*, 1993). Thus, the expression of a recombinant protein using pPIC can be controlled by the concentration of added methanol. In addition, protein production under this promoter can be performed in a higher-density culture environment than in the case of pGAP. Therefore, since a higher concentration of a recombinant protein solution is likely to be obtained under this promoter, the pPIC vector is typically the first choice. On the other hand, pGAP strongly induces the expression of recombinant protein in culture in the presence of glucose or glycerol as a substrate (Waterham *et al.*, 1997), so the target protein can be continuously and easily produced without changing to inductive culture. However, the density of cells tends to be limited, particularly in flask-scale culture, limiting the yield of the target protein.

Table 1 Fungal-derived recombinant enzymes expressed in *P. pastoris* by our group

Family	Protein	Source Organism	Reference
<i>Glycoside Hydrolase</i>			
GH1	β -glucosidase (<i>PcBgl1A</i>)	<i>Phanerochaete chrysosporium</i>	Tsukada <i>et al.</i> (2006)

Fig. 1 Experimental scheme for the expression of recombinant proteins in *P. pastoris*.

Strains

Many types of *P. pastoris* hosts are available, differing mainly in the availability of selectable markers, methanol assimilation rate, and the presence or absence of protease genes (Lin-Cereghino and Lin-Cereghino, 2007; Ahmad *et al.*, 2014). The availability of a selection marker need not be considered when selection is done with antibiotics, but is relevant when performing auxotrophy screening using amino acids.

The rate of methanol assimilation greatly affects whether the final recombinant protein production can be performed on a large scale in a fermenter or on a flask scale, particularly in the case of the methanol-induction (pPIC) system. The rate of methanol assimilation in *P. pastoris* depends on the presence or absence of a mutation in the alcohol oxidase *aox1* gene, and this trait is expressed as a methanol utilization phenotype (Mut). Many *P. pastoris* strains, including wild strains, can grow well with methanol as a carbon source (the Mut⁺ phenotype). Further, Mut⁺ strains can continue producing recombinant proteins for a long period even when only methanol is available as a carbon source. Consequently, large amounts of recombinant protein per batch can be produced. However, since Mut⁺ strains rapidly consume methanol in the culture solution, it is necessary to supply methanol continuously to achieve continuous induction. This is straightforward in cultivation using a jar fermenter, but in flask culture, methanol must be added at least every 12 h in order to maintain an inducing concentration, and this may be inconvenient. On the other hand, in the Mut^s phenotype, the AOX1 gene is partially deleted and replaced with the ARG4 gene of the yeast *Saccharomyces cerevisiae* (Cregg and Madden, 1987), and as a result, methanol consumption is slower than that of Mut⁺ strains. Consequently, Mut^s strains can maintain induction for a long time with the initially added methanol; for example, in flask-scale culture,

Fig. 2 Nucleotide sequences around the α -factor signal and the multi cloning site (MCS) of pPICZ α A.

supplementation of methanol once every 24 h is sufficient. However, the growth phase of Mut^s is shorter than that of Mut⁺ when only methanol is available as a carbon source. For the purposes of our research, we have usually found Mut^s strains more suitable.

Using Functional Host Strains

P. pastoris expression host strains with various functions are still being developed, including strains that can visually confirm the introduction of the recombinant gene (Thermo Fisher Scientific, PichiaPink™), that can mediate human-like glycosylation (Laukens *et al.*, 2015), that are easily adaptable for commercial purposes (ATUM, IP-Free® Cell Strains), etc. Among them, protease-deficient strains lacking one or several secretory protease genes are effective to protect recombinant products from proteolysis (Gleeson *et al.*, 1998). This is important, because degradation of recombinant proteins is a major problem in *P. pastoris* systems, especially when the production rate of the target protein is low. However, such gene-modified strains often have a lower productivity of recombinant protein than wild-type strain (Lin-Cereghino and Lin-Cereghino, 2007). Therefore, careful attention to the balance of production and degradation rates is required.

Vectors

Since the introduced plasmid vector is fused into the genome of *P. pastoris*, the recombinant strain is stable. We were able to produce recombinant proteins without addition of antibiotics even in a jar fermenter. This section describes the factors involved in the selection and construction of transformation vectors.

As described above, it is necessary to choose a suitable selection marker and promoter depending on the host species and induction system. For example, in selection with the antibiotic Geneticin 418 (G418) for the construction of multi-copy transformants, the initial selection based on histidine dependence requires a biosynthetic marker such as HIS4 in the pPIC9K vector (Clare *et al.*, 1991b). To use such selection system, it is necessary to select a host that supports multiple selections.

Secretory signals also play a very important role in the construction of recombinant strains. Various signal sequences have been investigated for secretory expression of heterologous proteins from *P. pastoris* (Raemaekers *et al.*, 1999; Kjeldsen *et al.*, 1999). In many commercial expression vectors, the sequence derived from α -mating factor of *S. cerevisiae* is adopted as a secretion signal. Fig. 2 shows the gene sequences around the α -factor signal and the multiple cloning site (MCS) sequence of pPICZ α (Invitrogen), which is often used in the construction of secretory expression strains. The α -mating factor protein is a secretory hormone of *S. cerevisiae*. The α -factor signal sequence in pPICZ α is composed of a 19-amino-acid signal peptide, which translocates the target protein into the endoplasmic reticulum (ER), and a 66-amino-acid preprotein sequence that induces coat protein complex II (COPII)-mediated vesicle transportation (Otte and Barlowe, 2004; Dancourt and Barlowe, 2010). When the target gene is inserted into the MCS region, the target protein is connected to the C-terminal of the α -factor signal protein via a recognition site for proteases Kex2 and Ste2 (Fig. 2 Pattern C). Recombinant protein synthesized in this way is transported to the ER by the action of the signal peptide sequence, then the preprotein is cleaved by Kex2 and Ste2 in the Golgi apparatus, and the target protein is secreted outside the cells (Julius *et al.*, 1983; Fuller *et al.*, 1988).

Introduction of the target gene into the MCS makes it possible to produce a secretory expression construct easily, regardless of the type of protein sequence. However, several additional amino acid residues derived from the vector and the remaining Ste2 protease recognition sequence are added to the N-terminus of the target protein when a gene is inserted into the MCS. Notably, the

number of amino acids derived from the Ste2 recognition sequence may be four residues (Glu-Ala-Glu-Ala-...), two residues (Glu-Ala-...) or none, due to the weak activity of Ste2 protease. Such amino acids that remain randomly at the N-terminal cannot be controlled during cultivation. Although such N-terminal heterogeneity does not affect the enzyme activity, the extra amino acids are problematic if a protein has an active site at the N-terminus (Koganesawa *et al.*, 2001; Daly and Hearn, 2005; Westereng *et al.*, 2011). Furthermore, if a recombinant protein is required for crystal structure analysis, this heterogeneity at N-terminus presents a serious problem, because crystallization may fail, or the crystal structure resolution may be reduced.

To avoid such problems, we routinely generate secretory constructs with no extra amino acids. For example, in the production of the Auxiliary Activities (AA) family 9 lytic polysaccharide monooxygenase (LPMO) from *Phanerochaete chrysosporium* in *P. pastoris*, the recombinant enzyme is active only when the natural N-terminal histidine of the enzyme is exposed (Westereng *et al.*, 2011). Subsequent structural analysis confirmed that this AA9 enzyme has an active site at the N-terminus, and that the enzyme activity requires coordination of a metal ion in the active site. We spent more than five years trying to identify the actual function of the enzyme just because of the effect of the extension generated from the MCS, indicating the importance of obtaining a recombinant enzyme as similar in structure as possible to the natural form, especially for a target protein whose function is not clear.

There are two ways to make a construct for secretory expression of a recombinant protein with the native N-terminal sequence, i.e., with a secretory signal sequence other than the α -factor signal (Fig. 2 Pattern A) or without the Ste2 protease recognition site after the α -factor signal (Fig. 2 Pattern B). In the case of pattern B, the target gene is introduced after the Lys-Arg sequence of the Kex2 protease recognition site located following the α -factor pre sequence. Since the Kex2 protease specifically cleaves the location immediately after the sequence, this construct can produce the target protein having a natural N-terminus. The secretory behavior is similar to that of the gene introduced using the MCS in this method, since the existing α -factor signal system can be used for transporting the translated protein to the ER. However, the type of N-terminal amino acid of the target protein affects the cleavage by Kex2 protease, because the substrate specificity of Kex2 depends on the amino acid at the recognition site (Manfredi *et al.*, 2016). In order to secrete a target protein incompatible with this restriction, it is necessary to use a secretory signal other than the α -factor signal.

In *P. pastoris*, it is possible to construct a secretory system using not only yeast-derived, but also non-yeast-derived enzymes, such as the yeast oligosaccharyl transferase subunit protein (OST1) signal, the yeast daughter cell-specific endo-1,3- β -glucanase (Dse4) signal, the plant lectin signal, the *Phaseolus vulgaris* agglutinin (PHA) signal, the *Rhizopus oryzae* alpha-amylase signal, and the human serum albumin signal (Forte *et al.*, 2011; Liang *et al.*, 2013; Raemaekers *et al.*, 1999; Li *et al.*, 2011; Xiong *et al.*, 2008). Predictive design of signal peptides is also underway with the aim of further improvement of productivity (Massahi and Çalık, 2016). Such a heterologous signal sequence is useful because it may have a secondary effect, such as increasing the expression level, though it is difficult to predict in advance what kind of signal sequence is likely to be effective for the expression of the target protein, and many combinations have to be tested. This uncertainty is an obstacle to applications of the *P. pastoris* system, because it is more laborious to construct a recombinant strain and to confirm target protein expression than in the case of *E. coli* systems. It is often necessary to use a trial-and-error approach.
